Abstract

We characterize how firms structure supply chains under climate risk. Using new data on the universe of firm-to-firm transactions from an Indian state, we show that firms diversify sourcing locations, and suppliers exposed to climate risk charge lower prices. Our event-study analysis finds that firms with suppliers in flood-affected districts experience a decline in inputs lasting two months, followed by a return to original suppliers. We develop a general equilibrium model of firm input sourcing under climate risk. Firms diversify identical inputs from suppliers across space, trading off the probability of a climate shock against higher input costs. We quantify the model using data on 271 Indian districts, showing real wages vary across space and are correlated with geography and productivity. Wages are inversely correlated with sourcing risk, giving rise to a cost minimization-resilience tradeoff. Supply chain diversification unambiguously reduces real wage volatility, but ambiguously affects their levels, as diversification may come with higher input costs. While diversification helps mitigate climate risk, it exacerbates the distributional effects of climate change by reducing wages in regions prone to more frequent shocks.

1 Introduction

The intersection of complex supply chains and climate risk presents a critical challenge to the global economy. While complex supply chains have yielded significant efficiency gains worldwide, enabling firms to procure inputs from the most efficient suppliers regardless of their location, escalating climate risk raises concerns about the vulnerability of global production networks and the ensuing broader economic fragility (Barrot and Sauvagnat, 2016; Boehm et al., 2019). Increasing global risk of climate change also heightens the likelihood of natural disasters such as flooding and storm surges. In response, forward-looking firms may choose their production locations (Castro-Vincenzi, 2024) or diversify the locations of their suppliers based on geographic variability in climate threats to mitigate the impact of disruptions to their productive activities. Therefore, our understanding of how climate change may reshape economic production and its implications for welfare across regions hinges on firms' adaptive sourcing decisions in response to escalating hazards. In this paper, we provide a theoretical, empirical, and quantitative analysis of the spatial consequences of supply chain restructuring in light of increased climate risk.

Studying the general equilibrium consequences of how firms structure supply chains when faced with climate hazards raises two important challenges. First, for empirical evidence on how firms respond to climate risk, we need high-frequency data on transactions along the supply chain, the precise locations of establishments, and meaningful variation in weather-related events. Second, to quantify the broader economy-wide consequences, we require a general equilibrium model of firm input sourcing under climate risk, where firms face trade-offs such as the lower probability of climate shocks against higher-cost, less productive inputs or higher shipping costs.

To address the first challenge, we obtain the universe of establishment-to-establishment level transactions from a large state in India, as long as one node of the transaction (either buyer or seller) is in the state (the other node can be anywhere in the country). This dataset contains the precise zip code of the establishments, the value of the transaction, the product code, the date, the quantity (and so the unit values), and the unique tax ID of the establishment. Using these data, we document important new facts suggesting firms are optimizing supply chains to mitigate climate risk. First, firms diversify the locations they source from, even within narrow product codes. And second, firms that multisource the same product buy from farther distances, dryer regions and pay higher prices. Third, suppliers in regions that are more exposed to climate risk tend to charge lower prices.

A key advantage of our setting is that India experiences monsoonal rainfall that follows a somewhat predictable spatial pattern every year, although the intensity and timing can

vary. Regions across India are regularly and increasingly experiencing large flooding events that disrupt firm supply chains. Firms operating in this environment might reasonably consider the probability of climate-related disruptions to their operations, as suggested by our descriptive analysis.

To provide causal evidence of firm responses to climate shocks, we leverage the exogenous geographic and temporal variation in flooding events using a staggered event study design. We show that the sales of flood-hit suppliers fall drastically over three months but recover by five months after a flood. Further, the total purchases of downstream buyers decrease substantially, and they are unlikely to substitute to other suppliers. Yet, we detect no change in the sales of these downstream buyers. Prices increase in the short run, but once again recover. Importantly, we show no difference in affected and unaffected firms in the pre-period. Our descriptive and event-study results together suggest firms plan for climate-related risk and recover from the realized shocks relatively quickly. These empirical patterns motivate and discipline our general equilibrium framework.

In addressing the second challenge of quantifying economy-wide impacts, we introduce a new theory. We build a spatial general equilibrium model of firm sourcing under climate risk. Motivated by our empirical results and the patterns in the data, firms diversify their sourcing of otherwise identical inputs across locations to mitigate climate risk. Such diversification comes with a trade-off: places with lower climate risk might be less productive, or geographically distant, necessitating payment of higher trade costs.

A key feature of the model is that firms' expected profit functions in the presence of sourcing risk are concave in input orders. That is, firms behave as if they are risk averse, even in the absence of explicit risk aversion in preferences. This implies that firms from each region will choose to diversify their input sourcing across regions if they face heterogeneous shock probabilities, even in the extreme case where regional fundamentals are constant across space, and trade is costly (a "symmetric" economy). In a comparative statics exercise, we show that in this setting, there might be no conventional gains from trade, but trade still occurs purely due to the diversification motives of firms. As a result, despite identical fundamentals, "safer" regions see higher real wages in general equilibrium, while more distant or riskier regions see lower real wages.

Interestingly, this comparative statics exercise implies that the prices of inputs and, therefore, of regional consumption, are higher under costly trade than regional autarky. A stark insight from this exercise is that the average expected regional real wage is lower under costly trade than under autarky, but its volatility is also lower. In other words, under commonly used consumer preferences that do not explicitly have a role for the volatility of real wages in welfare, in this exercise, costly trade is welfare decreasing. We show, how-

ever, that free trade in the symmetric economy brings both the diversification benefits of lower wage volatility and higher expected real wages compared to costly trade.

We quantify this model using a census of manufacturing firms across the country, allowing us to estimate location-specific productivities and labor shares. We implement the model on 271 districts in India. Our model implies that bilateral sourcing shares are a function of all regional labor endowments, productivities, and bilateral trade costs, as well as the risk of sourcing in each region. Given estimates of regional labor, productivity, and bilateral trade costs, we back out model-implied regional risk that is necessary to fit observed sourcing shares. To validate our framework, we project the model-implied risk on climate observables such as rainfall and floods as well as other risk-related variables such as court capacity to capture institutional features that affect firm decisions. We find that climate-related risk is positively correlated with the estimated risk probabilities. The positive correlation suggests that firms take into account several sources of risk when they form their supply chains, a feature that has been largely ignored by the literature (an exception is [Kopytov et al. \(2021\)](#) who study how supply chains adapt to supplier volatility).

While the comparative statics exercises provide stark analytical insights about the possible impacts of diversification, the effects of firm diversification in a realistic economy will, in general, depend on the variation in fundamentals and “standard” motives for trade, such as geography and productivity in addition to risk-mitigation incentives. Our third contribution is, therefore, quantitative: we compute expected real wages across districts in our calibrated model, given model-implied sourcing risk. Our framework implies that as a result of firm sourcing decisions, real wages in each district will depend on the geography, productivity, and climate risk of all districts.

We perform several quantitative exercises in our calibrated model. First, we validate the insight from our comparative statics exercises regarding wage volatility. We find that under the estimated trade costs and climate risk, the variance of real wages is 77% lower. On the other hand, expected real wages do not always have to be lower than in autarky. In our calibrated model, they are on average 5% higher, although 11% of districts see expected real wages that are lower than autarky. We then study how regional wages change in general equilibrium under alternative shock probabilities to capture scenarios of changing climate risk and to highlight our new channel. We map projections of changes in flood risk and precipitation risk to our estimated probabilities and compute expected real wages, input prices and wage volatility under the scenario of flood risk and precipitation risk increasing as projected. We find that the average risk of districts increases by 0.38pp, but there is wide heterogeneity. Expected real wages decline on average by 1%, but their volatility also declines on average by 1.14%. Safer districts largely see expected real wage increases. Our model and quantification show that firm sourcing decisions help mitigate

the effects of climate shocks and have quantitatively important implications in general equilibrium for real wages in safer regions relative to riskier ones.

Our results highlight two economic implications of climate change. On the positive side, the risks of climate change are mitigated since firms anticipate climate risk and diversify their sourcing decisions to minimize the volatility due to climate shocks. This implies that more volatile weather does not necessarily translate into higher aggregate output volatility. On the negative side, climate change will have even larger redistributive effects across regions than commonly believed. Regions with more climate risk will face the direct effects of the shocks themselves, but additionally will also become less appealing to other regions as a source of inputs. As a result, demand for products from these regions will decline, and real wages will fall. The converse will occur in “safer” regions. In other words, diversification will amplify the distributional effects of climate change.

Related literature. A growing literature studies how climate change shapes economic activity. Several papers focus on the long run, assessing how the distribution of economic activity changes within and across regions, and countries (Bilal and Rossi-Hansberg, 2023; Cruz and Rossi-Hansberg, 2023; Desmet et al., 2021; Hsiao, 2023; Jia et al., 2022; Nath, 2022). A smaller subset considers optimal medium-term policy responses (Balboni, 2021). Another branch of the literature studies the effects of extreme weather events on firms’ employment and location decisions as well as on FDI (Castro-Vincenzi, 2024; Gu and Hale, 2022; Indaco et al., 2020; Pankratz and Schiller, 2021). In this paper, we study the general equilibrium impacts of endogenous firm supply network decisions under climate risk. While we emphasize how firms can use their supply networks to mitigate the risk of extreme weather events, our model is well suited to analyze the general equilibrium effects of supply network formation under any location-specific risk.

While the responses of firm supply chains to climate risk have not received much attention in the literature, closely related to our paper is parallel work by Balboni et al. (2023), who study firm supply chains responses to flood events in Pakistan. While our empirical strategies are broadly similar, our data vary in that they contain information on establishment locations, detailed product codes, prices, and quantities, which enables us to estimate responses of a rich set of variables to shocks. Our model studies sourcing decisions and supply chains that are formed in anticipation of shocks, delivers strong implications for how wages across space are shaped by regional risk, and can be used to infer the risk that firms assign to different sourcing locations.

Our theoretical and quantitative results are also related to the insights in Kopytov et al. (2021), who study supply chain adaptation to supplier volatility, and to Pellet and Tahbaz-Salehi (2023), who study the implications of rigidities in supply chains that arise due to

incomplete information. [Caselli et al. \(2019\)](#) show that diversification across sectors can lower aggregate volatility in a quantitative trade model. Similar to the rigid inputs in [Pellet and Tahbaz-Salehi \(2023\)](#), firms in our model place orders for intermediate inputs prior to the realization of shocks, and cannot adjust their orders ex-post. In contrast to these papers, our model features households in multiple regions who cannot trade shares of the different firms, and the incentive to mitigate volatility arises from the concavity of firm profits. As a result, in our framework, aggregate volatility decreases in openness to trade, as firms mitigate risk. However, in our model, expected real wages can be lower under costly trade compared to autarky. This parallels the results in these papers that aggregate output is also lower due to diversification away from volatile suppliers. We show, however, that eliminating trade barriers permits both expected real wages and aggregate volatility to be lower, maximizing the benefits of diversification.

Supply chain fragility and resilience have received increased attention in the literature following the Covid-19 pandemic ([Goldberg and Reed, 2023](#); [Grossman et al., 2023](#); [Khanna et al., 2022](#)). Our firm-to-firm data are similar to [Khanna et al. \(2022\)](#), but our identification strategy uses extreme weather events, and we emphasize the adaptation of supply chains to climate risk and the general equilibrium consequences, which are not studied in that paper. Our empirical evidence indeed suggests that firm supply chain responses to climate-related risk vary qualitatively and quantitatively from their responses to an unanticipated, temporary shock like Covid-19.

Finally, we also build on a growing research agenda on how production networks respond to shocks. A long literature documents the importance of international trade in inputs and studies the macroeconomic consequences of such trade ([Antràs et al., 2017](#); [Caliendo and Parro, 2015](#); [Hummels et al., 2001](#); [Johnson and Noguera, 2012, 2017](#); [Yi, 2003](#)). A strand of this literature has emphasized the transmission of natural disasters through trade and supply chain links ([Barrot and Sauvagnat, 2016](#); [Boehm et al., 2019](#); [Carvalho et al., 2021](#)). In contrast to studying the responses of firms or sectors to the incidence of shocks, we quantify the general equilibrium economy-wide consequences of firm supply chain adaption to the (changing) probability of shocks.

The rest of our paper is structured as follows. [Section 2](#) outlines our data, shows descriptive patterns, and contains our event study analysis around flood events. [Section 3](#) sets up the model, derives some analytical results, and performs comparative statics. [Section 4](#) calibrates and quantifies the model, while [4.4](#) contains the climate change counterfactuals, and [Section 5](#) concludes.

2 Empirical Approach

2.1 Data

Firm-to-firm trade. Our primary data source is daily establishment-level transactions (while we use the term “firm”, the data are at the granular establishment level). These data are from the tax authority of a large Indian state with a fairly diversified production structure, roughly 50% urbanization rates, and high population density. Comparing this context to other contexts with firm-to-firm transaction data, we observe that the state has roughly three times Belgium’s population, seven times Costa Rica’s, and double Chile’s.

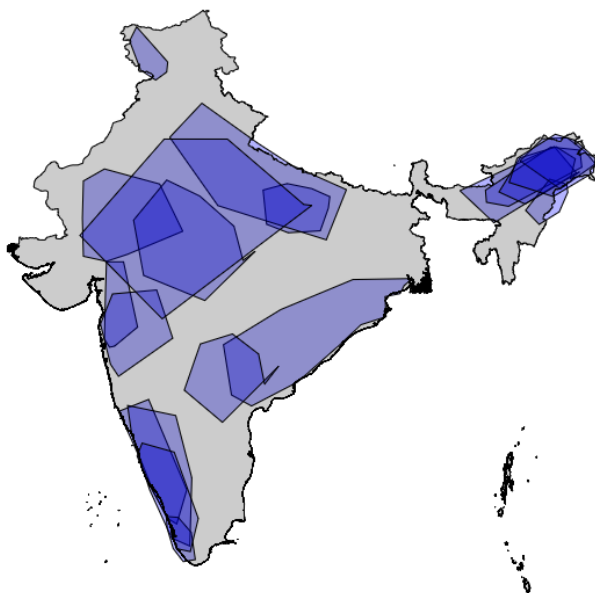

The data contain daily transactions from April 2018 to October 2020 between all registered establishments within the state, and all transactions where one node of the transaction (either buyer or seller) is in the state. All transactions have unique tax identifiers for both the selling and buying establishments, which include the value of the whole transaction, the value of the items being traded by 8-digit HSN code, the quantity of each item, its unit, and transportation mode.

Each transaction also reports the zip code location of both the selling and buying establishments, which we merge with other geographic data. By law, any goods transaction with value over Rs.50,000 (\$700) has to generate away-bills, which populate our data. Transactions with values lower than \$700 can also optionally be registered. As such, our network is representative of relatively larger firms, but the threshold is sufficiently low to capture small firms as well. More information is in Appendix C.1, with summary statistics in Table A1.

We use the data to construct the buyer-supplier network every period and the total value of inputs purchased and output sold by firms. To obtain a measure of real inputs and output, we use the reported quantity of each transaction to calculate unit values for each product, construct a price index, and deflate the total firm-level input purchases and sales. Our output measure is noisier than inputs, given that we do not observe direct-to-consumer sales. Therefore, whenever using output as an outcome, we restrict the sample to firms with positive sales every period before the flooding event began.

Climate data. We use data from the Dartmouth Flood Observatory to identify geocoded flooding events throughout India for our event study analysis. As shown in Figure 1, we identify 19 events of monsoonal rain throughout India between 2018 and 2021. For our event study analysis, we limit the set of floods to those that occurred outside of our state, and that caused at least 100 individuals to be displaced by the flood. These restrictions leave us with seven large flood events, which we use in our analysis in Section 2.3.

Figure 1: Monsoonal rain floods, 2018-2020

Note: The figure plots the geographic coverage of all large floods that occurred between 2018 and 2020, as described in the Dartmouth Flood Observatory.

We complement the climate-related datasets with information on district-level historical and projected daily rainfall, coastal flooding, riverine flooding and average temperatures. Details on this data can be found in Appendix C.1.

2.2 Descriptive Analysis

To begin our analysis, we document four facts related to supplier diversification and climate risk to motivate the key features of our model.

Fact 1: Even within narrow product categories, there is a significant mass of firms that source the same product from multiple regions.

We take advantage of the detailed product information in our transaction data and compute the number of districts a firm sources a given product from. As shown in Table 1 Column 1, 63% of the firms in our data buy from more than one district. In columns 2 to 4 we show that a significant fraction of firms also multisource the same product across regions. We compute the number of districts a firm-by-HSN product code pair sources from. In Column 2, we use 2-digit product codes; in Column 3, we use 4-digit product codes; and in Column 4, 8-digit product codes. Even with the narrowest product definition available in our data, 17.4% of firms source the same product from more than one district. This is evidence that a significant fraction of firms multisource their products.

Fact 2: Firms that have larger purchases of a given product are more likely

Table 1: Share of firms that source from multiple districts

Number of supplier districts	Share of buyers	Share of buyers x HSN 2	Share of buyers x HSN 4	Share of buyers x HSN 8
1	36.9%	65.8%	74.8%	82.6%
2	20.0%	16.2%	13.3%	9.7%
3	11.8%	6.4%	4.4%	2.3%
4	7.5%	3.1%	1.8%	0.8%
5	5.1%	1.7%	0.9%	0.4%
6	3.6%	1.1%	0.5%	0.2%
7	2.6%	0.7%	0.3%	0.1%
8	1.9%	0.4%	0.2%	0.1%
9	1.5%	0.3%	0.1%	0.1%
+10	9.2%	4.2%	3.7%	3.8%

Note. Column 1 aggregates the data at the firm level and computes the share of firms that source from a certain number of districts. Column 2 aggregates the data at the firm-by-2-digit product level, Column 3 at the firm-by-4-digit product level, and Column 4 at the firm-by-8-digit product level.

to source from multiple regions.

We rank all firm-by-8-digit HSN pairs into percentiles, based on total purchases, where the higher percentiles include the firm-product pairs with the higher purchase volume. As shown in Figure 2, the smallest firm-product pairs tend to only source from a single supplier. However, towards the end of the distribution, the largest firm-product pairs source, on average, from more than one region. Firms above the 95th percentile source, on average, from two districts, and firms in the top percentile source from four. This suggests that larger, more productive firms are more likely to multisource.

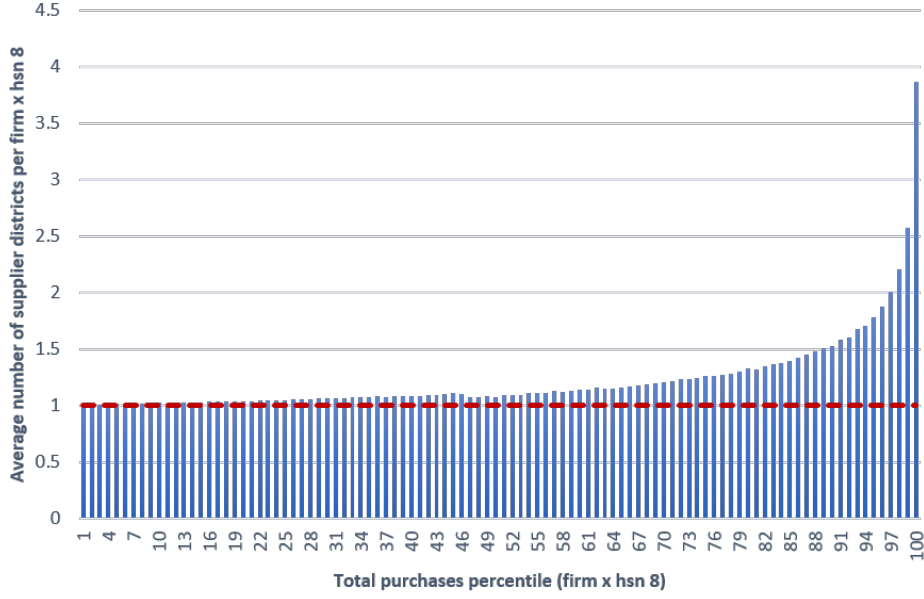

Fact 3: Firms that multisource more tend to buy products from farther distances, slightly dryer regions, and pay higher input prices.

Once again, we focus on firm-product pairs using the 8-digit product classification. In Figure 3a, we show that firms that source the same product from more regions tend to buy from suppliers that are farther away. For instance, firm-product pairs that source from one district have an average distance of 350 km to suppliers. On the other hand, firm-product pairs with five suppliers per product have an average distance of almost double, at 700 km.

In Figure 3b, we also show that firm-product pairs with more suppliers also seem to source from less rainy districts. For firm-product pairs that source from one district, such districts have, on average, a 10.9 mm daily rainfall. On the contrary, for firm-product pairs that source from five districts, such districts have, on average, 10 mm of daily rainfall. The average daily rainfall across all Indian districts is 8.11 mm, so the difference between those sourcing from one versus five districts is 11% with respect to the mean.

Finally, in Figure 3c, we show that firms that source from more districts also tend to pay

Figure 2: Number of supplier districts by total purchases

Note. We rank all firm-product pairs into percentiles (1-100) based on the volume of total purchases in 2019. For each percentile (in the horizontal axis), we compute the average number of districts the firm-product pairs source from.

higher prices for their inputs. To compute average prices, we first run a regression of log price on product fixed effects, and standardize the residual of such regression to construct our residual price index. We then normalize the average price for those firms that source from only one region to one. As shown in Figure 3c, firms that source from 5 districts pay an average price that is 0.6 standard deviations higher than firms that source from only one district. The average price paid monotonically increases with the number of districts sourced from.

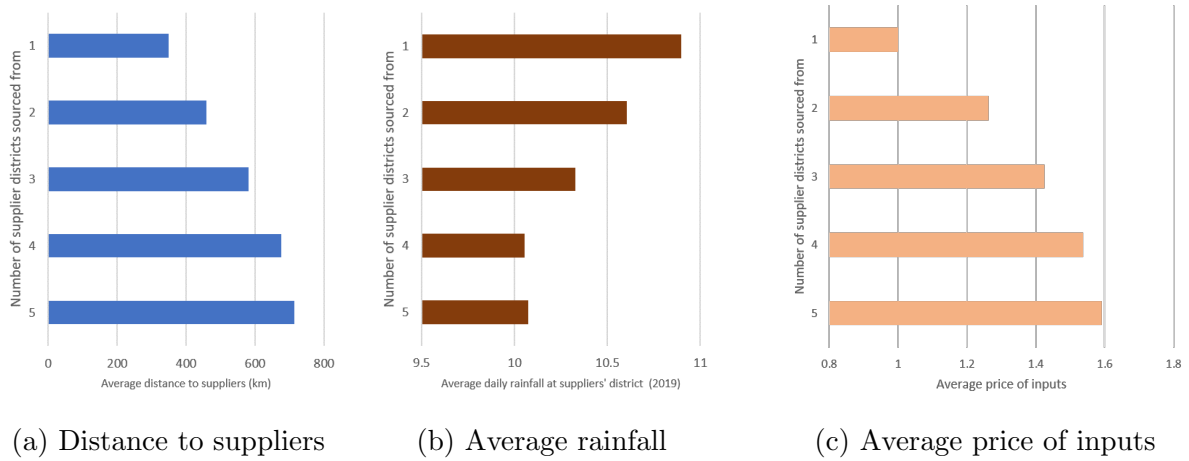

Fact 4: Supplier districts that face higher climate risk charge lower prices.

Figures 3b and 3c suggest that as buyers purchase from more suppliers, they source from regions with lower climate risk and pay higher prices. The flip side of this pattern is that suppliers in riskier areas might charge lower prices. To investigate this relationship further, we run a regression at the buyer (j) - supplier district (d) - product (p) level as in equation 1.

$$\log(\text{Price})_{j,d,p} = \alpha_1 \log(\text{Climate risk})_d + \alpha_2 \log(\text{Distance})_{j,d} + \alpha_3 \mathbb{1}(j \text{ in } d) + \alpha_4 \mathbb{1}(j, d \text{ in same state}) + \gamma X_{d,p} + \delta_j + \delta_p + \epsilon_{j,d,p}, \quad (1)$$

where $\log(\text{Price})_{j,d,p}$ is the log of the average price charged to buyer j for product p by suppliers in district d . We control for the distance between j and d , indicators on whether the buyer is in district d or the same state as district d , and a set of controls at the

Figure 3: Supplier characteristics by number of districts sourced from

Note. In the left panel, we compute the average distance between the firm and each of its suppliers from our transaction data. We then compute the average distance across firm-product pairs sourcing from 1 to 5 districts. In the middle panel, for each firm-product pair, we compute the average daily rainfall at each of the districts the firm sources from. Daily rainfall comes from the India Meteorological Department. We then compute the average across all firm-product pairs sourcing from 1 to 5 districts. In the right panel, we compute the average price paid for inputs for firm-product pairs sourcing from 1 to 5 districts. To construct our price index, we first run a regression of log prices on product fixed effects and take the residual. We standardize the residual and normalize it to 1 for firm-product pairs that source from only one district.

product-supplier district level ($X_{d,p}$) such as the log size of all supplier sales from that district-product pair and the log of the total sales from that district. We also include buyer and product fixed effects, so the identification of the climate variables comes from firms that buy from multiple districts. Additionally, we include covariates that aim to capture market power at the supplier district, such as the log of the total number of suppliers for a given product in the district and the log of the largest supplier market share for that product in the district.

We consider two climate risk measures: the average daily rainfall for each district in 2019 and the historical river flooding in each district. Details on how these climate variables are computed can be found in Appendix C.1. As shown in Table 2, both climate measures are negatively correlated with prices. The magnitudes are robust to including additional controls at the supplier-district level. A 10% increase in rainfall in a district, is associated with suppliers in those districts charging 0.11% lower prices. Similarly, a 10% increase in riverine flooding levels in a district is associated with 2.55% lower prices charged by suppliers in that district. While these results cannot be interpreted as causal, they are suggestive that riskier areas do charge lower prices.

Table 2: Correlation between price and supplier district climate risk

	Log (Price) _{j,d,p}	Log (Price) _{j,d,p}		Log (Price) _{j,d,p}	Log (Price) _{j,d,p}
Log(Avg Daily Rainfall in d)	-0.0179*** (0.005)	-0.0112** (0.005)	Log(Avg River Flooding in d)	-0.381*** (0.026)	-0.255*** (0.026)
N obs	991,802	991,802	N obs	996,720	996,720
Additional controls	No	Yes	Additional controls	No	Yes

Note. *** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$. We run a cross-sectional regression at the firm (j), supplier district (d), 8-digit product (p) level. The outcome is the log of the average price charged by suppliers in district d , to firm j for product p . The first and third columns control for log average distance between j and suppliers in d , a dummy variable for whether j is in district d , a dummy variable for whether j is in the same state as d , the log of total sales in product p from suppliers in d , the log of total sales of suppliers in d across all products, buyer fixed effects and product fixed effects. Columns 2 and 4 include additional controls for the log number of suppliers for product p in d and the log market share of the highest supplier in product p . Climate variables used are average daily rainfall in district in 2019 (left panel) and historical riverine flooding levels in district (right panel).

2.3 Event-Study Analysis

We proceed by documenting how firms respond to climate-driven supply chain disruptions. We leverage the timing of these unexpected weather shocks to examine how sales and purchases change in the lead-up to and right after the shock. Our goal is to isolate the effect of the shock from other determinants that drive changes in sales and purchases.

Our event-study analysis allows us to examine pre-trends in the lead-up to the shock, and dynamics thereafter. The absence of pre-trends may provide suggestive evidence that our parallel-trends identification assumption is likely to hold, whereas the post-shock dynamics are informative of how long it takes for firms to recover after the flood.

First, we study how the shock directly affected suppliers in flood-hit regions. Then, we use the existing supplier network (in the pre-shock period) as a measure of the exposure to the shock, to study how buyers were affected when their suppliers were hit. Intuitively, we want to compare two firms that face the same trends in demand and productivity and only differ in the location of their suppliers. By comparing the observed disruptions of a firm whose suppliers were more exposed to floods with a similar firm whose suppliers were less exposed, we can isolate the impact driven by supply chain disruptions.

Effects on suppliers in flood-hit regions. We begin with documenting the direct effect on suppliers in flood-hit zones with the specification, where we examine outcomes $y_{j,t,k,\tau}$ for firm j , in period t , and industry k , measured in event-time (since flood) τ :

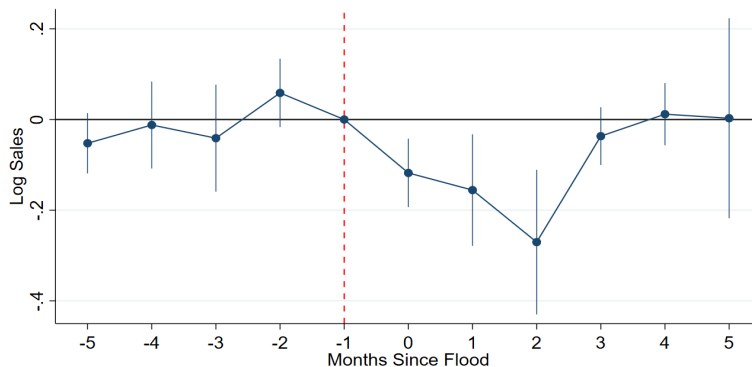

$$y_{j,t,k,\tau} = \sum_{x=-5}^{x=+5} [\alpha_x \mathbb{1}(\text{Exposed to flood})_{j\tau} + \delta_{\tau,x} + \beta_x X_{j,\tau_0-1}] + \delta_j + \delta_{k,t} + \epsilon_{j,t,k,\tau}. \quad (2)$$

Here, the variable “Exposed to flood _{$j\tau$} ” takes a value of 1 if firm j was exposed to a

particular flood. We include a wide range of high-dimensional fixed effects to account for confounding shocks. These include firm fixed effects δ_j that control for firm-specific time-invariant differences; industry-by-time fixed effects $\delta_{k,t}$ that control for industry-specific shocks; and flood event-time since flood fixed effects $\delta_{\tau,x}$ that control for aggregate trends around the flood event that affect all firms (including those not in the flood-exposed areas). We also control for firm size-specific shocks, by controlling for purchases in the pre-period X_{j,τ_0-1} , interacted with time-since flood indicators. The sample consists of firms that had positive sales in the month before a flood.

Figure 4 plots α_x , which are time dummies that capture the differential impacts on firms that were directly exposed to the flood, relative to other (non-flood-hit) firms that had positive sales in the month before a flood. The figure shows a lack of meaningful pre-trends in the lead-up to the flood. After the flood, there is an immediate decline in sales of 0.11 log points, which worsens until two months after the flood. About two months after the flood, sales are about 0.25 log points lower than baseline sales. After the two-month slump in sales, there is a quick recovery, and four months after the flood, sales recover to what they were in the pre-period.

Figure 4: Sales of affected suppliers

Note. Event-study specification documenting sales of firms that were exposed to floods in month= 0. The specification includes firm, time, event-time, and industry-real time fixed effects, and log pre-period sales-time controls. Standard errors clustered at the district level.

Effects on downstream firms. To examine how buyers are affected, we need to first define a buyer’s exposure to the floods. We define a firm j ’s supplier exposure to be how exposed its suppliers were to the flood:

$$(\text{Supplier Exposure})_{j\tau} = \sum_i^N s_{i,j,\tau_0-1} \times \mathbb{1}(\text{Supplier } i \text{ exposed to flood in } \tau) ,$$

where s_{i,j,τ_0-1} is the value of purchases that firm j buys from firm i , relative to firm j ’s total purchases, just before the flood. The index, essentially, calculates the weighted

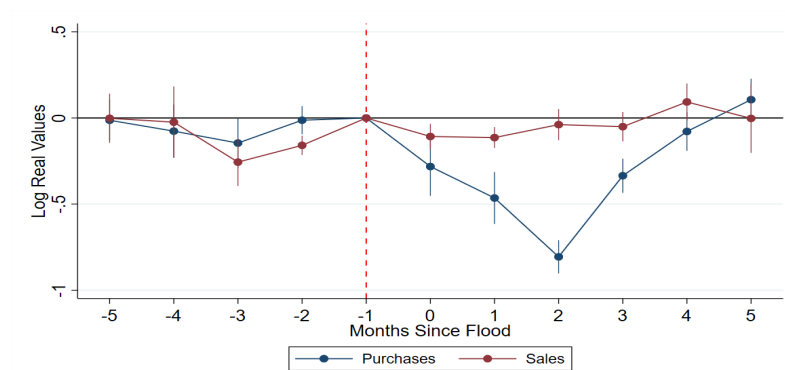

average of the flood exposure of firm j 's sellers. A higher value of the index implies firm j faces a higher “supplier-exposure,” as a larger share of its purchases were coming from firms exposed to the flood. The exposure measure has a mean of 0.018 and standard deviation of 0.1.

With the help of this variable, we can now study the outcomes $y_{j,t,k,\tau}$ of downstream firms j in period t , industry k , and time-since flood τ :

$$y_{j,t,k,\tau} = \sum_{x=-5}^{x=+5} [\gamma_x (\text{Supplier Exposure})_{j\tau} + \delta_{\tau,x} + \beta_x X_{j,\tau_0-1}] + \delta_j + \delta_{r,k,t} + \epsilon_{j,t,k,\tau}. \quad (3)$$

Once again, we control for firm-specific time-invariant factors δ_j ; industry-by-district-by-time fixed effects $\delta_{k,r,t}$ that control for industry-by-region specific shocks; and flood event-time since flood fixed effects $\delta_{\tau,x}$ that control for aggregate trends around the flood event that affect all firms. X_{j,τ_0-1} , interacted with time-since flood indicators, controls for firm size-specific shocks.

Figure 5: Purchases and sales of downstream firms

Note. Event-study specification documenting sales and purchases of downstream firms that were exposed to floods in month=0. The specification includes firm, time, event-time, and industry-district-real time fixed effects, and log pre-period sales-time controls. Standard errors clustered at the district level.

Figure 5 plots coefficients γ_x , which are time indicators that capture the differential outcomes (sales or purchases) of downstream firms with higher supplier risk. Once again, the coefficients in the pre-periods do not display any meaningful trends, suggesting that perhaps high- and low-exposed firms had similar trends, at least in the pre-flood period.

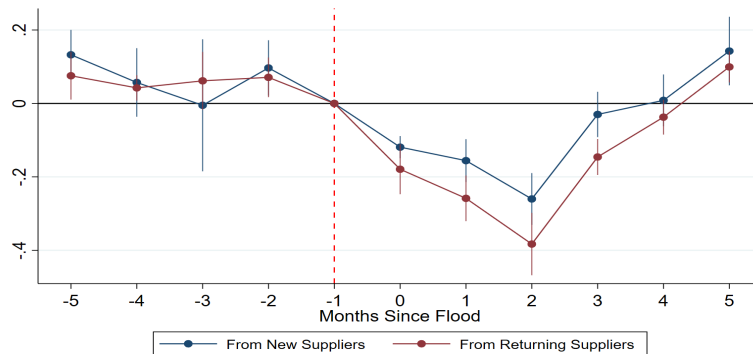

Consistent with Figure 4, we find that purchases decline sharply for the first few months, and then start to recover. Purchases are the lowest at two months after the flood dropping by 0.078 log points with respect to the baseline period, for every one standard deviation increase in the supplier exposure (standard deviation of exposure is 0.1). Purchases recover to the pre-period levels by four months after the flood. This pattern follows closely with what happens to the sales for directly affected suppliers in Figure 4. We later revisit this

estimate to calibrate how inputs are disrupted in our model quantification.

Interestingly, however, Figure 5 also shows that the sales of downstream firms are relatively modestly affected and only decrease by 0.009 log points the month following the flood, for a 1SD increase in exposure. This rebounds quickly. Inventories of output or intermediate inputs could explain this divergence in the effects on output relative to inputs. Unfortunately, our data do not contain information on inventories, so we cannot empirically assess their role here. We develop a model extension in Appendix B.3, illustrating how intermediate input inventories can generate a divergence in the response of sales and inputs following a shock, consistent with the patterns here.

New suppliers vs. existing suppliers. Suppliers that are hit by temporary shocks may induce buyers to seek out new suppliers. We compare what happens to purchases from new suppliers and existing suppliers in Figure 6 to examine this switching behavior. The blue line shows that, if anything, there is a temporary fall in purchases from new suppliers as well. There is, as expected, a meaningful fall in purchases from existing suppliers, which recovers strongly eventually. In general, buyers are unlikely to create new links, and they instead revert back to their existing suppliers after the shock abates. These patterns are consistent with evidence from the same context that highlights how buyer-supplier relationships are personalized as relationship-capital is important (Cevallos Fujii et al., 2023), and as a result, firms are unlikely to switch to other suppliers in the face of temporary shocks (Cevallos Fujii et al., 2021).

Figure 6: Purchases from existing or new suppliers

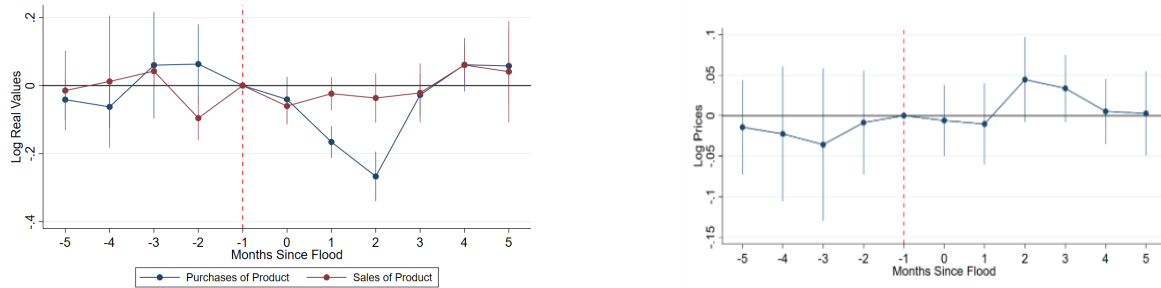

Note. Figures include firm, time, event-time, and industry-district-real time fixed effects, and demand controls and log pre-period purchases-time controls. Standard errors clustered at the district level.

Products and prices. An advantage of our version of the firm-to-firm trade data is that it has detailed product codes and unit values. This allows us to examine product-specific trades and changes in prices as a result of upstream suppliers being exposed to a shock. We first transform the data to the buyer-by-product-by-time level. Figure 7a shows the

results of shocks to upstream suppliers on the sales and purchases of downstream buyers. Our specification is similar to Equation 3, but with a product dimension that allows us to include event-time, industry-district-product-time, and firm-by-product fixed effects, along with controls for pre-period firm-by-product sales interacted with time indicators. Figure 7a shows similar patterns to before: downstream purchases fall, even as sales of downstream firms do not change substantially.

Figure 7: Product-level trade and prices

(a) Product-Level Purchases and Sales

(b) Changes in Prices

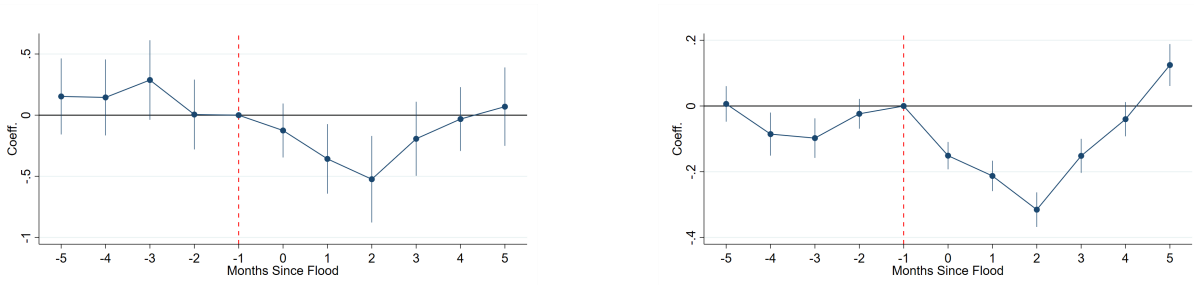

Note. Figure 7a includes event-time, industry-district-product-time, and firm-by-product fixed effects, along with controls for pre-period firm-by-product sales interacted with time indicators. Figure 7b includes product-time, firm-product, and event-time fixed effects. Standard errors clustered at the district level.

In Figure 7b, we study the evolution of product-specific prices for transactions that occur around the flood. While noisier, there seems to be an increase in price levels two months after the flood, but they recover and return to the baseline levels four months since the flood event.

New advances in two-way fixed effects methods. Recent econometric advancements in two-way fixed effects methods point out that staggered treatment can lead to the negative weighting of certain disaggregated treatment effects (Goodman-Bacon, 2018). New methods developed by Borusyak et al. (2021); Callaway and Sant’Anna (2020); Sun and Abraham (2020) provide consistent and interpretable estimates. Yet, our setting offers some further challenges. Our “treatment” (index) is continuous, turns “off” and “on” and perhaps “on” again, and our specifications control for various time-varying covariates, and a wide variety of other fixed effects, making none of these new advances a suitable benchmark in our setting. A new Local Projections Difference-in-Differences (LP-DID) estimator developed by Dube et al. (2023) allows us to recover interpretable estimates in a flexible and efficient manner.

We present the results from this LP-DID estimator, which show similar patterns. In implementing this method, we need to take a stand on using the continuous treatment variable, or a more conventional discretized one. We first study purchases for buyers

Figure 8: Linear Projection DID: Purchases for Buyers

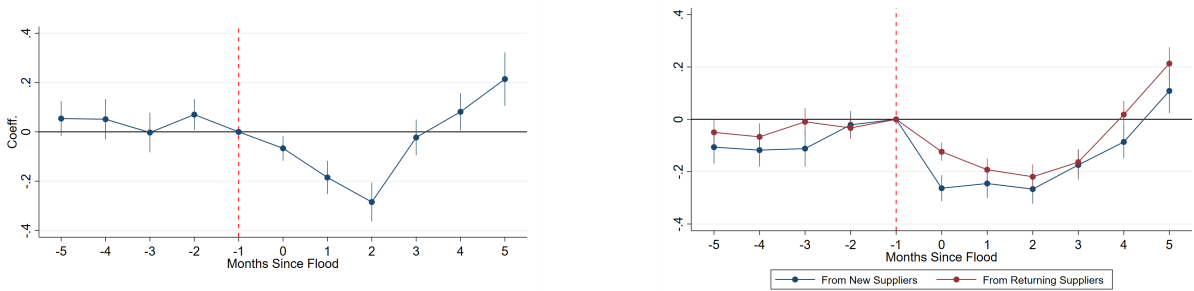

(a) LP-DID Continuous

(b) LP-DID Discrete

Note. Specification includes firm, flood, and industry-district-month fixed effects. Controls include log pre-period purchases interacted with time indicators. Figure 8b discretizes the treatment variable, by being equal to 1 if more than 5% of weighted purchases were from affected suppliers. Standard errors clustered at the district level.

in Figure 8a using the continuous treatment variable. In Figure 8b, we discretize the treatment variable, and once again reproduce the same pattern as before: purchases fall for the first few months, and thereafter recover by month 4.

Figure 9: Linear projection DID: other outcomes

(a) Sales of Affected Suppliers

(b) Buyer Purchases from Suppliers

Note. Figure 9a includes firm, flood, and month-by-industry fixed effects. Figure 9b includes firm, flood, and industry-district-month fixed effects. Controls include log pre-period purchases interacted with time indicators. Figures discretizes the treatment variable by being equal to 1 if more than 5% of weighted purchases were from affected suppliers. Standard errors clustered at the district level.

The results from the LP-DID method qualitatively resemble our main results for all other outcomes as well. Figure 9a shows the sales of affected suppliers, and Figure 9b contrasts existing vs. new suppliers. These patterns once again show that sales of affected suppliers fall, and that purchases from buyers decrease from both new and existing suppliers.

3 Model

This section develops a spatial general equilibrium model of firm sourcing under risk and performs comparative statics. Section 4 calibrates and quantifies the model.

3.1 Setting.

The economy consists of I regions. Each region is endowed with L_i workers, a unit continuum of final goods producers who produce nontraded final goods, and competitive intermediate goods producers.

Timing. The model is static and consists of two stages. In the first stage, final goods producers in each location i place their orders for intermediate inputs from location j , M_{ji} . In the second stage, inputs are produced, sourcing disruption shocks are realized, and then inputs are delivered. Final goods firms choose their labor inputs and produce, households supply labor and consume, and all markets clear at equilibrium prices.

Households. The household in region i supplies labor L_i inelastically to firms in i and consumes a CES aggregate of the non-traded regional final goods q_i with elasticity of substitution $\sigma > 1$. It solves

$$\max_{q_i(\omega)} \left(\int_{\omega \in [0,1]} q_i(\omega)^{\frac{\sigma-1}{\sigma}} d\omega \right)^{\frac{\sigma}{\sigma-1}}$$

such that

$$\int_{\omega \in [0,1]} p_i(\omega) q_i(\omega) = w_i L_i, \quad (4)$$

where $p_i(\omega)$ is the price of final good $q_i(\omega)$, and w_i is the wage in region i . Our baseline model assumes labor is immobile across regions.

Intermediate goods producers. In each region, there are a continuum of competitive suppliers of tradable intermediate inputs M_i with production function $M_i = z_i \ell_i^M$, where z_i is their productivity. The price of intermediates in i is equal to their constant marginal cost, $p_i^M = \frac{w_i}{z_i}$.

Let p_{ji}^M denote the price of intermediates from j used in i . We assume iceberg trade costs τ_{ji} between regions. No arbitrage in shipping implies that the price “at the factory gate” and the price at the time of intermediate usage are related by: $p_{ji}^M = \tau_{ji} p_j^M$.

Final goods firms. Each region i contains a unit continuum of homogenous final goods producers that produce differentiated varieties ω . Final goods are not tradable across regions. The constant returns to scale production function of the firms is

$$q_i(\omega) = \phi_i \ell_i(\omega)^\beta x_i(\omega)^{1-\beta}, \quad (5)$$

where ϕ_i is the productivity of final goods' producers in location i , $\ell_i(\omega)$ is the firm's labor input, and intermediates $x_i(\omega)$ can be sourced from each region $j \in I$ as perfect substitutes:¹

$$x_i(\omega) = \sum_{j \in I} x_{ji}(\omega).$$

Second stage. In the second stage, final goods firms have already placed their orders of intermediates $M_{ji}(\omega)$, shocks have been realized, and production takes place. The profit maximization problem of a final goods firm in i in the second stage is

$$\max_{q_i, \{x_{ji}\}_{j=1}^I, \ell_i} [Y_i \mathbb{P}_i^{\sigma-1}]^{\frac{1}{\sigma}} q_i(\omega)^{\frac{\sigma-1}{\sigma}} - w_i \ell_i(\omega) \quad (6)$$

$$\text{such that } x_i(\omega) = \sum_{j \in I} x_{ji}(\omega) \quad (7)$$

$$x_{ji}(\omega) \leq \chi_j M_{ji}(\omega) \quad \forall j, \quad (8)$$

and the production function (5). Here, Y_i is income, and \mathbb{P}_i is the price index in region i . $\chi_j \leq 1, j \in I$ are the shock realizations. We assume the shocks destroy some of the orders of inputs M_{ji} that have been placed in the region in the first stage, and so if a shock materializes, the firm receives fewer inputs than its order. This captures the notion of climate-associated shocks such as rainfall or floods, and we will calibrate the shock size to match our event study estimates in Section 2.3. We assume the stochastic shocks are origin-specific, and so they affect orders of inputs from all buying regions. As the shocks are not idiosyncratic, they will potentially affect aggregate outcomes.

Note that as second-stage profits (6) are monotonically increasing in input usage $x_i(\omega)$, the firm will always optimally use all available inputs that are delivered of its orders $M_{ji}(\omega)$. In other words, Equation (8) will always hold with equality.

The first order conditions of the firm's second stage problem (6) pin down a firm's optimal choices of labor ℓ_i , as well as its price p_i , quantity q_i , and profits π_i as a function of the vectors of first stage orders $\mathbf{M}_i = \{M_{ji}\}_{j=1}^I$ and origin-specific shocks, $\boldsymbol{\chi} = \{\chi_j\}_{j=1}^I$. In particular, the expression of profits for a firm in region i , suppressing the variety index ω for concise exposition, is:

¹Alternatively, we could also use an aggregator of K varieties of inputs, where inputs of the different regions are perfect substitutes within a variety. For simplicity, our baseline model uses a single "variety" of input that can be sourced from multiple regions.

$$\pi_i(\mathbf{M}_i; \boldsymbol{\chi}) = \left[\frac{\sigma(1-\beta) + \beta}{\beta(\sigma-1)} \right] \left[\frac{\beta(\sigma-1)}{\sigma} \right]^{\frac{\sigma}{\beta+\sigma(1-\beta)}} w_i^{\frac{\beta(1-\sigma)}{\beta+\sigma(1-\beta)}} \left[[Y_i \mathbb{P}_i^{\sigma-1}] \phi_i^{\sigma-1} \left(\sum_{j \in I} \chi_j M_{ji} \right)^{(1-\beta)(\sigma-1)} \right]^{\frac{1}{\beta+\sigma(1-\beta)}}. \quad (9)$$

First stage. In the first stage, prior to the realization of shocks, final goods producers in all locations choose their orders M_{ji} of inputs to maximize expected profits. Firms have rational expectations and make their input sourcing decisions based on the true joint distribution of origin-specific disruption shocks, $G(\boldsymbol{\chi})$.² The firm's problem in stage one is

$$\max_{M_i \geq 0} \mathbb{E}_{\boldsymbol{\chi}} (\pi_i(\mathbf{M}_i; \boldsymbol{\chi})) - \sum_{j \in I} p_j^i M_{ji}, \quad (10)$$

where p_j^i is the order cost of inputs from j in i , and $\pi_i(\mathbf{M}_i; \boldsymbol{\chi})$ is as in Equation 9. The first order conditions of this problem are

$$\mathbb{E}_{\boldsymbol{\chi}} \left(\chi_j \Theta_i \left[\sum_{j \in I} \chi_j M_{ji} \right]^{\frac{-1}{\beta+\sigma(1-\beta)}} \right) \leq p_j^i \quad \forall j, \quad (11)$$

where $\Theta_i = \left[\frac{(1-\beta)}{\beta} \right] \left[\frac{\beta(\sigma-1)}{\sigma} \right]^{\frac{\sigma}{\beta+\sigma(1-\beta)}} w_i^{\frac{\beta(1-\sigma)}{\beta+\sigma(1-\beta)}} \left[[Y_i \mathbb{P}_i^{\sigma-1}] \phi_i^{\sigma-1} \right]^{\frac{1}{\beta+\sigma(1-\beta)}}$ is a function of equilibrium aggregates that are potentially stochastic, as Y_i , w_i , and \mathbb{P}_i might depend on the shock realizations across regions.

These first order conditions highlight that when placing an order for intermediate inputs of a given origin j , firms equate marginal benefits and marginal costs. Moreover, this optimality condition elucidates under which circumstances the firm does not source from a particular location. This occurs if the expected marginal benefit from placing an infinitesimal order in location j , with optimal orders elsewhere, is strictly smaller than its price, p_j^I .

Proposition 1 *Ex-ante profits are concave in orders of inputs M_{ji} .*

Proof. See Appendix B. ■

This property of the firm's problem is important for the firm's optimal sourcing strategy. Interestingly, it implies that the firms behave as if they are risk averse, even without

²In our empirical implementation of the model, we assume that these shocks are binary, occurring with probability ρ_i in each location i , and independent across regions. However, our quantification of the model can accommodate alternative shock structures and spatially-correlated shocks.

explicit risk aversion in consumer or managerial preferences. In fact, firms are fundamentally risk-neutral. As a result, the “risk-aversion” through the concavity in profits will imply firms will optimally diversify sourcing locations.

3.2 Ex-Post General Equilibrium

In the second stage, shocks are realized, inputs are delivered across regions, and all goods and labor markets clear. The labor market clearing condition for each region i is

$$\underbrace{L_i - \frac{\bar{M}_i}{z_i}}_{\tilde{L}_i, \text{ Final goods labor}} = \left[\frac{\beta(\sigma - 1)}{\sigma} \frac{1}{w_i} [Y_i \mathbb{P}_i^{\sigma-1}]^{\frac{1}{\sigma}} \left(\phi_i \left(\sum_{j \in I} \chi_j M_{ij} \right)^{1-\beta} \right)^{\frac{\sigma-1}{\sigma}} \right]^{\frac{\sigma}{\beta + \sigma(1-\beta)}}, \quad (12)$$

where \tilde{L}_i is the labor used in the production of final goods in i , and $\frac{\bar{M}_i}{z_i}$ is the labor used in the production of $\bar{M}_i = \sum_{j=1}^J \tau_{ij} M_{ij}$ intermediates to ship to all regions $j \in I$ from region i .

Goods markets clear in each region implying that the region’s income is equal to its expenditure

$$Y_i = w_i L_i + \hat{\Pi}_i, \quad (13)$$

where $\hat{\Pi}_i$ are the aggregate profits in i of the final goods firms as in Equation (6) less their intermediate goods order costs

$$\hat{\Pi}_i = \int \pi_i(\omega) d\omega - \int \sum_j p_{ij}^I M_{ij}(\omega) d\omega. \quad (14)$$

Notice that we assume firms pay for their orders of intermediate inputs, not for the fraction they receive after the shock. Additionally, Equation (12) implies that the full quantity of intermediates ordered in stage 1 is produced. This implies that the shocks “destroy” a fraction of produced inputs.³

Features of the equilibrium. As all firms in a region are homogeneous, under the unit mass of firms assumption, the regional price index $\mathbb{P}_i = p_i$, and aggregate profits $\hat{\Pi}_i = \hat{\pi}_i$. We can then characterize several features of the equilibrium.

³We do not observe actual contracts between firms in the data, so we have to make an assumption regarding what fraction of the orders of inputs are paid for. Our setup would remain tractable under alternative assumptions, e.g. only a fraction of the order is paid for upfront. While that would change the input costs entering Equation (10), it would not change the concavity of first stage profits in order costs, which is the key mechanism for firm input diversification in this framework.

Lemma 1 *Aggregate profits are a constant fraction of labor income $\hat{\Pi}_i = \frac{1}{\sigma-1}w_iL_i$. Further, aggregate expenditure on materials in i is given by*

$$\sum_j p_{ij}^I M_{ij} = \frac{(1-\beta)(\sigma-1)}{\sigma} Y_i. \quad (15)$$

Proof. See Appendix B. ■

These properties imply that aggregate income in location i is given by

$$Y_i = \frac{\sigma}{\sigma-1} w_i L_i, \quad (16)$$

and that the share of labor used in producing final goods in region i is constant

$$\frac{\tilde{L}_i}{L_i} = \beta. \quad (17)$$

Equation (17) has strong implications for equilibrium wages. In particular, equilibrium wages need to be such that the remaining workers are allocated to the intermediate inputs sector in stage 1.

Lemma 2 *Equilibrium wages w_i are deterministic.*

Proof. See Appendix B. ■

In the ex-post general equilibrium, the expression for Θ_i which is part of the marginal contribution to profits of a marginal unit of M_{ij} (Equation 6) is given by the following expression

$$\Theta_i = (1-\beta)w_iL_i \left(\sum_{j \in I} \chi_j M_{ji} \right)^{-\frac{(1-\beta)(\sigma-1)}{\beta+\sigma(1-\beta)}}.$$

This implies that Θ_i is stochastic from the perspective of firms in stage 1. In fact, the only aggregate variable that is stochastic, varying with the realization of shocks, is the ideal price index, \mathbb{P}_i .

3.3 Ex-Ante General Equilibrium

As pointed out above, the vector of wages in each location, is deterministic and determined at the first stage. Since aggregate labor demand by final goods' producers is a constant fraction of the labor endowment, $\tilde{L}_i = \beta L_i$, wages must be such that intermediate goods producers employ $(1-\beta)L_i$ workers in input production. In turn, due to the linear technology assumption, it must be the case that in equilibrium, the production of

intermediates in each location is equal to $M_i = (1 - \beta)z_i L_i$. In the equilibrium of this economy, the vector of wages, $\{w_i\}_{i=1}^I$, must be such that total demand from intermediate goods producers in each region exactly equals this amount.

From re-arranging the trade balance and the optimal total intermediates expenditure conditions, one can derive the following equilibrium system, which generates the equilibrium vector of wages,

$$w_j L_j = \sum_i w_i L_i s_{ji}(\{w_i\}_{i=1}^I) \quad ; \quad s_{ji}(\{w_i\}_{i=1}^I) = \frac{\frac{w_j \tau_{ji}}{z_j} M_{ji}(\{w_i\}_{i=1}^I)}{\sum_\ell \frac{w_\ell \tau_{\ell i}}{z_j} M_{\ell i}(\{w_i\}_{i=1}^I)} \quad \forall j \in I,$$

where crucially, the matrix of sourcing shares defined by $\left\{s_{ji}(\{w_i\}_{i=1}^I)\right\}_{i=1, j=1}^I$ is a function of the vector of wages, the parameters of the model and the probability distribution of the shocks.⁴ This completes the description of the economy.

3.4 A Two Location Example

To gain intuition, consider a simple case with two locations. Region 1 is risky and receives a shock $\chi_1 < 1$, with probability ρ , and region 2 is a safe location.⁵ Additionally, there are no trade costs, and therefore, the optimal intermediate bundle chosen by firms is the same in both locations.

We further assume that intermediates are cheaper in the risky location, that is $p_1^I < p_2^I$. Notice that this must hold in equilibrium, because otherwise, the safe location dominates the risky location, and the labor market will not clear in the risky location.⁶

The optimal stage 1 sourcing choices of firms in all regions from both regions $i \in 1, 2$ is

$$M_{i1} : \rho \chi_1 \Theta_i^S [\chi_1 M_{i1} + M_{i2}]^{\frac{-1}{\beta + \sigma(1-\beta)}} + (1 - \rho) \Theta_i^{NS} [M_{i1} + M_{i2}]^{\frac{-1}{\beta + \sigma(1-\beta)}} = p_{i1}^I \quad (18)$$

$$M_{i2} : \rho \Theta_i^S [\chi_1 M_{i1} + M_{i2}]^{\frac{-1}{\beta + \sigma(1-\beta)}} + (1 - \rho) \Theta_i^{NS} [M_{i1} + M_{i2}]^{\frac{-1}{\beta + \sigma(1-\beta)}} = p_{i2}^I, \quad (19)$$

where $\Theta_i^S = \frac{(1-\beta)(\sigma-1)}{\sigma} Y_i (\chi_1 M_{i1} + M_{i2})^{-\frac{(1-\beta)(\sigma-1)}{\beta + \sigma(1-\beta)}}$ and $\Theta_i^{NS} = \frac{(1-\beta)(\sigma-1)}{\sigma} Y_i (M_{i1} + M_{i2})^{-\frac{(1-\beta)(\sigma-1)}{\beta + \sigma(1-\beta)}}$.

As discussed above, Θ_i is stochastic, and depends on whether or not the shock materializes in region 1. Under the monopolistic competition assumption, all firms take these

⁴Similar non-linear systems of equations in wages appear in several static trade models. Note that here, the system includes orders of intermediates M_{ij} which are also equilibrium objects and do not have a closed form solution.

⁵That is, $\mathbb{E}_\chi^1 = \rho \chi_1 + (1 - \rho)$ and $\mathbb{E}_\chi^2 = 1$.

⁶The fact that in this simple case, we have an interior solution for firms in both locations does not hold in general when there are multiple locations and trade costs.

aggregates as given. Plugging these shifters into the first order conditions of the firms, we can solve for optimal orders as a function of wages:

$$M_{i1} = \frac{(1 - \beta)(\sigma - 1)}{\sigma} Y_i \left[\frac{1 - \rho}{p_{i1}^I - \chi_1 p_{i2}^I} - \frac{\rho}{p_{i2}^I - p_{i1}^I} \right] \quad (20)$$

$$M_{i2} = \frac{(1 - \beta)(\sigma - 1)}{\sigma} Y_i \left[\frac{\rho}{p_{i2}^I - p_{i1}^I} - \frac{(1 - \rho)\chi_1}{p_{i1}^I - \chi_1 p_{i2}^I} \right]. \quad (21)$$

Let wages in the less risky region 2 be the numeraire. As intermediates are priced at marginal cost and from the labor market clearing condition (Equation 12), a constant fraction of labor is used in the production of intermediates, we can show that equilibrium wages in the risky region 1 are given by

$$w_1 = \frac{z_1 z_1 L_1 \chi_1 + z_2 L_2 (1 - \rho(1 - \chi_1))}{z_2 z_1 L_1 (\rho + \chi_1 (1 - \rho)) + z_2 L_2}. \quad (22)$$

3.5 Comparative Statics

For a larger number of regions, the model does not have an analytical solution. Prior to a full calibration to districts in India in Section 4.2, we first illustrate the model's properties in a stylized 3-region setting.

To narrow the focus to the role of varied risk across space in firm sourcing decisions, we assume the regions are homogenous in the productivity of their firms ϕ_i , their labor endowment L_i , and the productivity of their intermediate goods producers z_i . Trade is costly between regions and increasing in distance with elasticity 0.1. Finally, we assume that if a shock occurs, 90% of the inputs ordered are destroyed ($\chi = 0.1$).

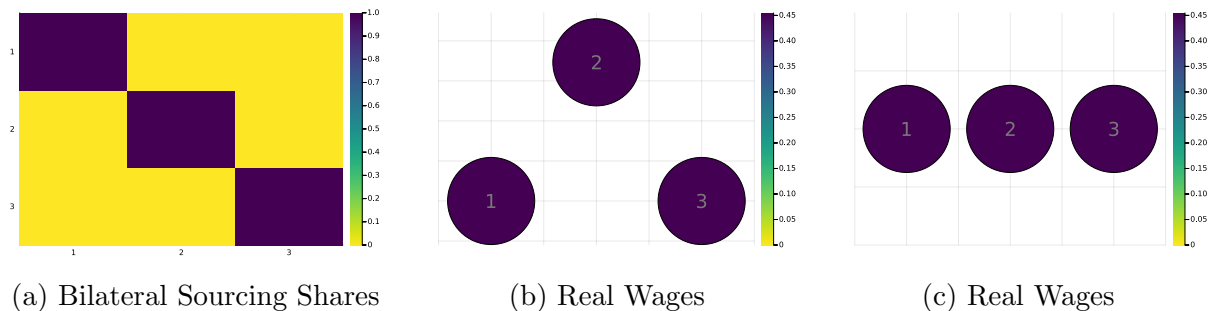

We consider two situations. First, we look into the case where the three locations are equidistant from each other. Second, we allow for regions to also vary in their distance to each other. The results for the first scenario highlight how firms diversify their suppliers without the feature that some suppliers are closer than others. The second adds geography as an additional margin that affects input sourcing choices. For stark comparative statics, we place the three regions on a straight line. This allows for a possible trade-off between the diversification motive and higher trade costs of sourcing from farther regions. In some experiments, we also vary the probabilities of shocks across regions.

We consider five experiments. In the first, “no risk” experiment, we assume $\rho_i = 0$ for all regions. In the second, “homogeneous risk” case, we assume a constant shock probability across space. That is, we assume $\rho_i = 0.15$ for all i . In the third, “heterogeneous risk” scenario, we assume the shock probability varies across space, with the average shock probability the same as the homogeneous risk case ($\frac{1}{3} \sum_{i=1}^3 \rho_i = 0.15$). In the fourth,

“heterogeneous risk in autarky” case, we raise trade costs to infinity, effectively prohibiting interregional input sourcing. In the fifth, “heterogeneous risk with free trade” case, we set trade costs to 0 across regions. The probabilities of shocks in cases four and five are the same as in the baseline heterogeneous risk case 3.

Case 1: No Risk. Figure 10 illustrates the sourcing shares and expected real wages when $\rho = 0$ for all regions. With identical fundamentals and positive trade costs, it is optimal for every firm to source all inputs domestically within its own region. This is true regardless of geography. Figure 10a illustrates the diagonal terms are 1, i.e., within-region sourcing shares are 1 for all regions, and cross-region sourcing shares are zero. The figure also makes clear that expected real wages are equalized across all regions under both geographies. This setting benchmarks our model relative to typical trade and spatial models where there is no sourcing risk. As all regions are identical, there are no gains from trade, and the equilibrium is regional autarky. In particular, the contrast between equidistant regions and regions on a line does not change either sourcing shares or regional real wages. There is no role for geography in the equilibrium with no risk and positive trade costs.

Figure 10: Scenario with no risk

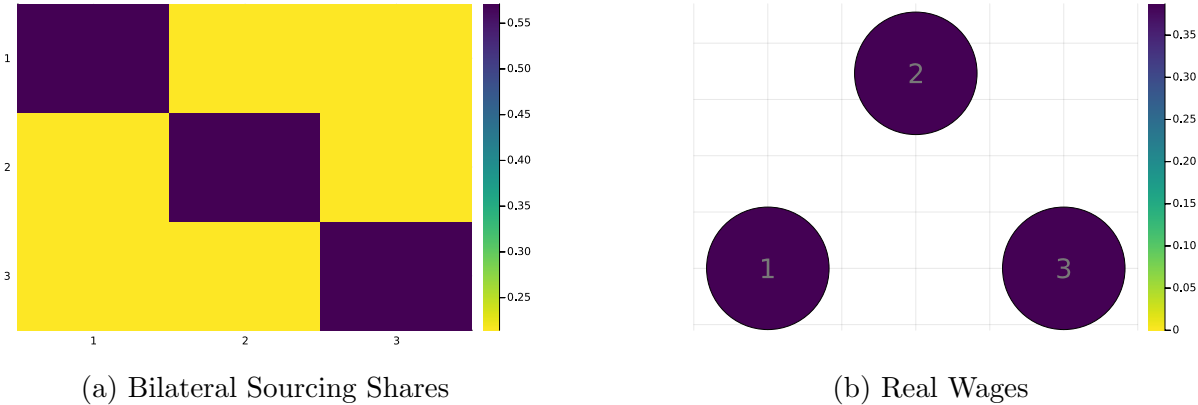

Note. Panel A shows the 3x3 input-output matrix where the buying regions are in the vertical axis and the supplying regions are in the horizontal axis. Each row represents the share of inputs purchased by a buying region from each (column) supplying region. In the scenario with no risk, the sourcing shares in Panel A are the sourcing shares for the geographies in Panels B and C. Panels B and C present the real wages for each region, as well as a visual representation of the geographical location of regions in space. In Panel B, regions are equidistant from each other. In Panel C, regions are in a straight line, implying that the regions have different distances from each other.

Case 2: Homogeneous Risk. Figure 11 illustrates the bilateral sourcing shares when the risk of shocks in each region is $\rho = 0.15$. Firms now face a trade-off: as shocks are independent across regions, they can reduce the probability of input disruptions by sourcing from multiple regions. On the other hand, sourcing from other regions is costly, due to the trade costs. As a result, firms still largely source inputs from their own regions, but also diversify by sourcing some inputs from geographically closer regions where trade costs are lower. Panel B illustrates that this higher demand for inputs

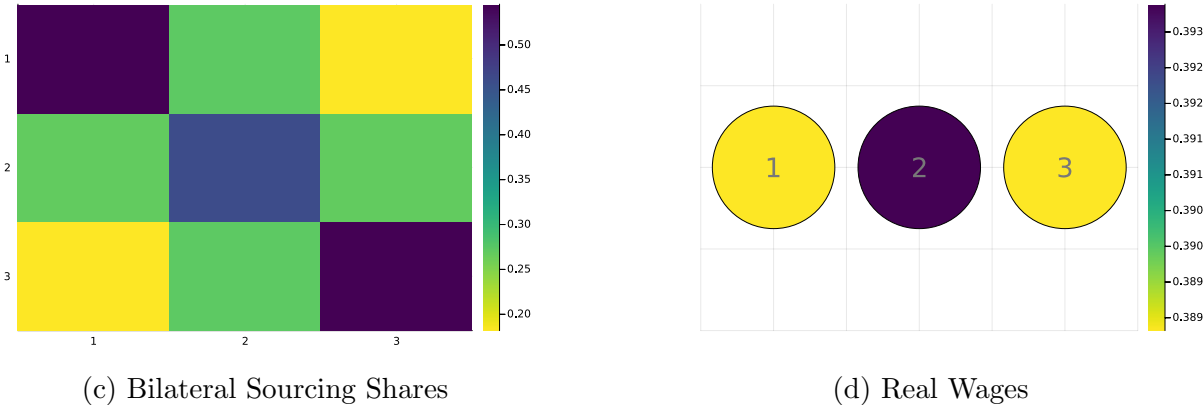

from more central regions in equilibrium results in higher expected real wages in these regions. These more central regions also diversify their risk the most by participating in interregional sourcing. Note that the expected price index in more central regions is therefore lower in equilibrium, as firms from these regions pay less in trade costs for inputs and better diversify risk. In contrast, Panel A shows that while firms diversify risk with some interregional sourcing, there is no geographic variation in expected real wages or in sourcing patterns with equidistant regions.

Figure 11: Scenario with homogeneous risk

Panel A: Same distance between regions

Panel B: Different distance between regions

Note. The figures in the left panel consist of a 3x3 input-output matrix where the buying regions are in the vertical axis and the supplying regions are in the horizontal axis. Each line represents the share of inputs purchased by a buying region from each supplying region (column). The figures in the right panels present the real wages for each region, as well as a visual representation of the geographical location of regions in space. In Panel A, regions are equidistant from each other. In Panel B, regions are in a straight line, such that the regions have different distances between each other. The scales are shown to the right of each figure.

Case 3: Heterogeneous Risk. The left panels of Figure 14a illustrate the regional maps and the shock probabilities of each region in the heterogeneous risk case under both equidistant regions and heterogeneous distance. The middle panels show the bilateral

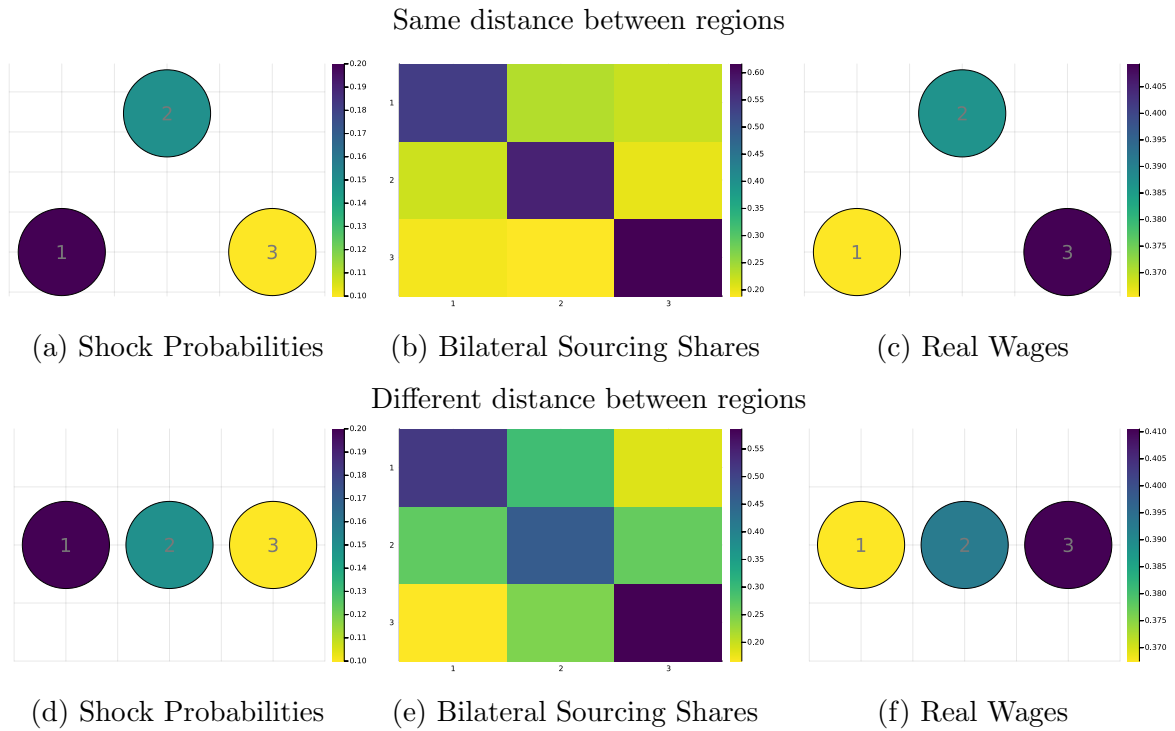

sourcing shares between regions. The diagonal is again the darkest, in the presence of trade costs all regions source most of their inputs from their own region despite heterogeneous risk. However, there is clear variation. Region 1, the riskiest region, has the smallest “own sourcing” share in both geographies while the safest region 3 sees the most “own sourcing.” All regions source inputs from other regions, with relatively larger shares from those with low risk. Geography plays an important role too. In the top panel, with equidistant regions, the riskiest region 1 has a high sourcing share from the safest region 3. With regions on a line in the bottom panel, however, region 1 is now farther from the safe region, and so its sourcing share from region 3 decreases.

The right panels show that expected real wages across regions are negatively correlated with the risk of shocks, and are highest in safest locations despite identical regional fundamentals. The underlying mechanisms at work are that safer regions experience higher labor demand for their intermediate inputs from all regions, pushing up nominal wages. They also face a lower price index of their final goods, as they can source safer “domestic” inputs without paying trade costs. Notice that in general equilibrium, the wage impacts on safer regions will modulate sourcing from them. As a result, even with equidistant regions, the safe region does not see the highest sourcing shares from all other regions.

Importantly, under our assumption that inputs are perfect substitutes and that regions have identical fundamentals, there is no source of traditional gains from trade either through comparative advantage or increasing varieties. The incentives for trade here arise entirely to mitigate risk, with strong spatial general equilibrium implications for wages and prices. We will return to this point below, when evaluating the welfare gains from supplier diversification.

Comparison between homogeneous and heterogeneous risk cases. Figure 13c compares the expected real wages and their variance between the homogeneous and heterogeneous risk cases. The left panels show the ratio of expected real wages, and the right panels show the ratio of their variance. As is immediately clear, the riskiest region 1 has the largest declines in its expected real wages as we move from homogeneous to heterogeneous risk under both geographies, while the safest region 3 has lower expected real wages under homogeneous risk. Region 2, which has the same risk under both homogeneous and heterogeneous risk, sees relatively higher expected real wages when risk is heterogeneous *and* it is a central region (bottom panel). In this instance, while it is not the safest region, it is still attractive as a sourcing destination due to its central location. When it is equidistant from all regions (top panel), its expected real wages are similar between trade and autarky. The right panels of the figure show that all regions

Figure 12: Scenario with heterogeneous risk

Note. The figures in the left panel show the probability that each region is hit by a shock, as well as a visual representation of the geographical location of regions in space. The figures in the middle panel consist of a 3x3 input-output matrix where the buying regions are in the vertical axis and the supplying regions are in the horizontal axis. Each line represents the share of inputs purchased by a buying regions from each supplying region. The right panels present the real wages for each region. For the top panels, regions are equidistant from each other. In the bottom panels, regions are in a straight line, such that the regions have different distances between each other. The scales are shown to the right of each figure.

see a decline in the variance of their expected real wages in the heterogeneous risk case relative to homogeneous risk. The safest region 3 sees some of the largest declines, as its shock probability decreases moving to heterogeneous risk. However, the decline in expected wage variance for region 3 is larger when it is equidistant from all regions and can diversify its risk at lower cost, than when it is farther away (bottom panel). The riskiest region 1 also sees a larger decline in its wage variance when it is equidistant from all regions and can diversify its higher risk at lower cost, than when it is farther away from the safest region 3 (bottom panel). On the other hand, region 2 sees a larger decline in wage variance when regional distance is heterogeneous, as it benefits from its central location and better ability to diversify risk at lower cost.

Case 4: Heterogeneous Risk and Autarky. We next maintain the heterogeneous risk across regions but raise trade costs to infinity, shutting down interregional input sourcing. Figure 14 illustrates that while the probabilities of shocks remain the same as Case 3 above (left panel), bilateral sourcing mimics the no-risk Case 1 (middle panel). However, the impact on expected real wages is very different in both Case 1 and Case

Figure 13: Comparison between homogeneous and heterogeneous risk cases

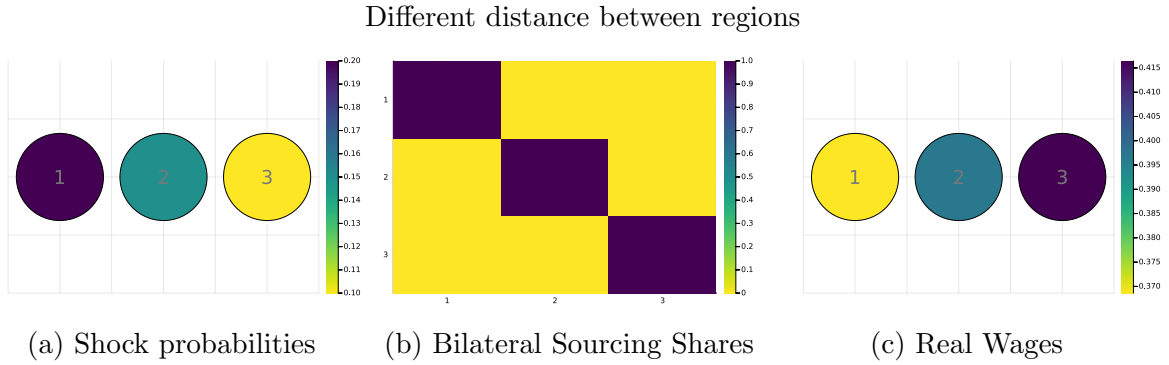

Note. In this figure we plot the expected real wages (left panel) and variance of real wages (right panel) for the homogeneous case shown in Figure 11 relative to the heterogeneous case shown in Figure 12. The variance of real wages is computed across potential states of the world. For the top panels, regions are equidistant from each other. In the bottom panels, regions are in a straight line, such that the regions have different distances between each other. The scales are shown to the right of each figure.

3 (right panel). The riskiest region sees the lowest expected real wages, while the safest regions see the highest expected real wages, as they have the lowest expected prices due to the lowest shock probabilities and fully domestic sourcing. The range of expected real wages is larger in this case than with costly trade, illustrating the diversification benefit of trade in mitigating expected real wage inequality across regions in an environment with risk. In Appendix B, we show that the expected real wage patterns are similar for equidistant regions, as with autarky, regional geography has no impact on regional outcomes.

Welfare comparison between costly trade and autarky with heterogeneous risk cases. We next consider how expected real wages change across regions moving from costly trade to autarky in Panel A, Figure 15. Interestingly, all regions see a decline in

Figure 14: Scenario with heterogeneous risk and infinite trade costs

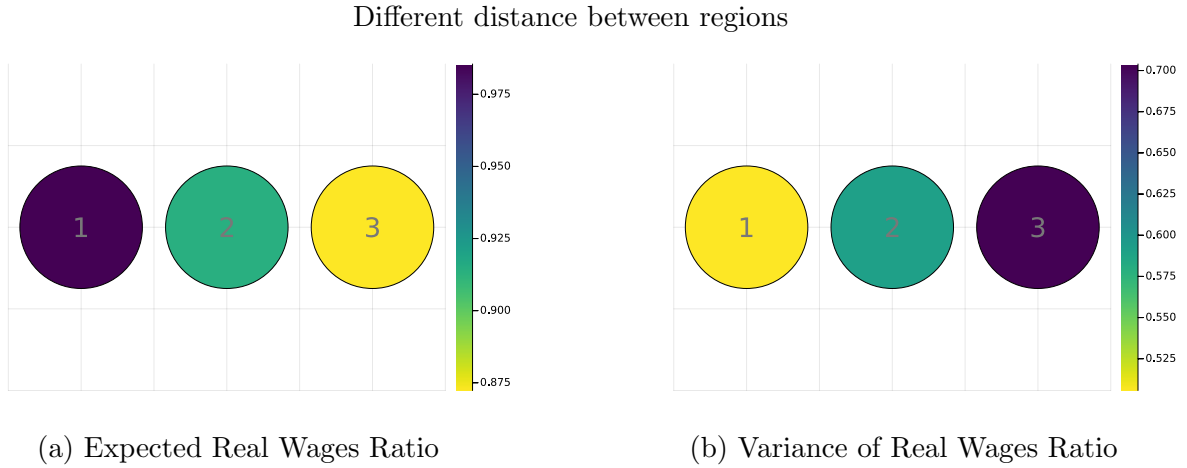

Note. This figure presents the case where trade costs are set to infinity. The figures in the left panel show the probability that each region is hit by a shock, as well as a visual representation of the geographical location of regions in space. The figures in the middle panel consist of a 3x3 input-output matrix where the buying regions are in the vertical axis and the supplying regions are in the horizontal axis. Each line represents the share of inputs purchased by a buying regions from each supplying region. The right panel presents the expected real wages for each region. The scales are shown to the right of each figure. In this scenario, regions vary in their distance and are located on a line. The case with equidistant regions is shown in Figure A2.

expected real wages moving to trade from autarky. The intuition is that in this setting, there are no “conventional” gains from trade, as there is no comparative advantage or gains from variety. The primary reason for trade here is for risk diversification. However, trade is costly, so the benefits of diversification are obtained at a higher average input price, raising regional price indices and lowering expected real wages under costly trade. The smallest decline in real wages is for the riskiest region 1, which is due to its expected real wages being relatively low in autarky as well as its high shock probability.

While the diversification motive for trade does not improve welfare as measured by the expected real wage, Panel B of the figure illustrates that the variance in real wages increases sharply, moving to costly trade from autarky for all regions. Supply chain diversification lowers the variance in final goods prices across all regions, insuring against shocks and real wage volatility. Again, the riskiest region 1 sees the largest increase in the variance of expected real wages when trade is barred. Appendix Figure A3 shows the same insight holds with equidistant regions, as regional geography primarily modulates sourcing patterns when trade is possible, but does not otherwise play a large role in the mechanisms underlying the relative decline in real wages and increase in their variance moving from costly trade to autarky.

Case 5: Heterogeneous Risk and Free Trade. Under free trade, firms can diversify their input risk at lower costs – the trade-off is only that inputs in lower-risk regions will be more costly in equilibrium as those regions will see higher expected real wages. With the same fundamentals across regions and free trade, in equilibrium, every firm

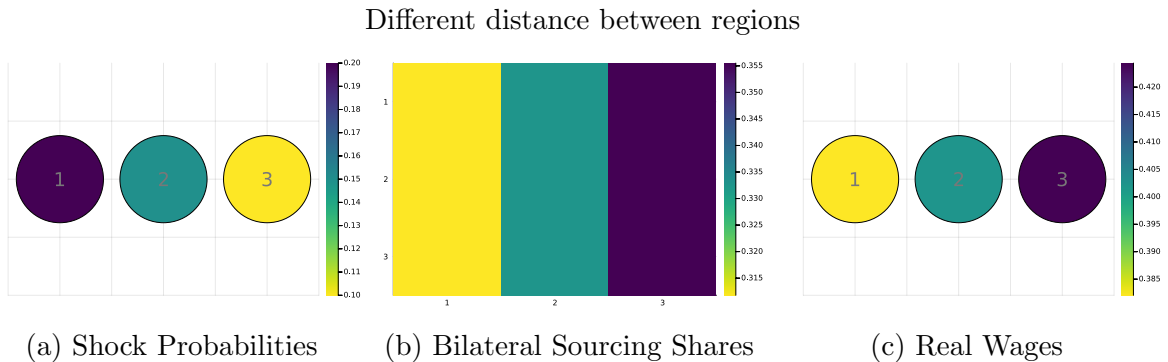

Figure 15: Comparison between heterogeneous risk under costly trade and autarky

Note. In this figure we plot the expected real wages (left panel) and variance of real wages (right panel) for the scenario with heterogeneous risk and costly trade shown in Figure 12 relative to the scenario with heterogeneous risk and trade autarky shown in Figure 14. The variance of real wages is computed across potential states of the world. Here, regions are in a straight line, such that the regions have different distances between each other. The scales are shown to the right of each figure. The case with equidistant regions is shown in Figure A3.

in every region has the same optimal sourcing strategy. The middle panel of Figure 16 illustrates these sourcing shares. The left panel illustrates that in this setting, there is increased expected real wage dispersion relative to costly trade, as sourcing concentrates in the safest location region 3, pushing up real wages there. Under free trade, regional geography plays no role in these patterns, and sourcing shares and expected real wages are the same as in this case when regions are equidistant (Figure A4).

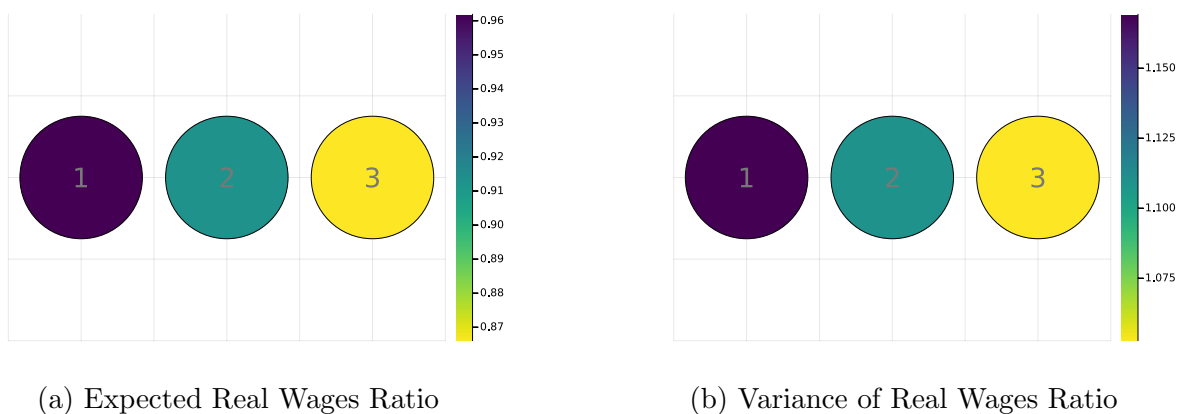

Figure 16: Scenario with heterogeneous risk and free trade

Note. This figure presents the case where there are no trade costs. The figure in the left panel shows the probability that each region is hit by a shock, as well as a visual representation of the geographical location of regions in space. The figure in the middle panel consists of a 3x3 input-output matrix where the buying regions are in the vertical axis and the supplying regions are in the horizontal axis. Each line represents the share of inputs purchased by a buying regions from each supplying region. The right panes present the real wages for each region. The scales are shown to the right of each figure. Figure A4 illustrates the case when regions are equidistant from each other.

Welfare comparison between costly and free trade with heterogeneous risk. Panel A of Figure 17 illustrates that in contrast to costly trade, all regions see higher expected real wages under free trade. This is due to the lower costs of inputs, both from risk diversification and the lack of trade costs. The largest increases in expected real wages moving from costly to free trade are in the safer but geographically-distant region 3. This region sees increases in sourcing from all regions as firms no longer face high trade costs to access the region’s lower risk inputs, but also sees larger declines in its own price index as its firms do not pay large trade costs to diversify their own risk. Panel B illustrates that moving from costly to free trade also lowers the variance of expected real wages across all regions. Thus, under free trade, there is no trade-off between higher expected real wages and lower volatility. Similar insights hold when regions are equidistant (Figure A5).

Figure 17: Comparison between costly and free trade

Note. In this figure we plot the expected real wages (left panel) and variance of real wages (right panel) for the scenario with heterogeneous risk and costly trade shown in Figure 12 relative to the scenario with heterogeneous risk and free trade shown in Figure 16. The variance of real wages is computed across potential states of the world. Here, regions are in a straight line, such that the regions have different distances between each other. The case with equidistant regions is in Figure A5. The scales are shown to the right of each figure.

4 Quantification

4.1 Solution Approach

The solution to the quantitative model introduced in Section 3 requires overcoming three computational challenges. First, the perfect substitutability across intermediate inputs from different origins, combined with the existence of trade costs, implies that the solution to the firms’ sourcing problem may not necessarily be interior; that is, firms in some regions might find it optimal not to source intermediates from certain origins. Second, finding the solution to the firms’ optimal sourcing problem involves computing a high-dimensional

expectation over 2^I states of the world.⁷ Third, the two challenges mentioned above are compounded by the need to find the equilibrium of the model, which essentially surmounts to finding the vector of wages for which all markets clear.

Given a vector of wages, $\{w_i\}_{i=1}^I$, and shock probabilities, $\{\rho_i\}_{i=1}^I$, we leverage the structure of the model to solve it efficiently. The first property of the problem described in Equation 10 is that the objective function is concave, and that the constraints are linear. Thus, any locally optimal point is also globally optimal, i.e., the Karush-Kuhn-Tucker (KKT) conditions are both necessary and sufficient for global optimality. These allow us to solve the firm's problem by combining the stationarity and complementary slackness conditions to find that at the optimum, the following condition:

$$\mathbb{E} \left(\chi_i \Theta_j \left[\sum_{i=1}^I \chi_i M_{ij} \right]^{\frac{-1}{\beta + \sigma(1-\beta)}} \right) M_{ij} = \frac{w_i \tau_{ij}}{z_i} M_{ij} \quad \forall i \in I,$$

which results from multiplying the first order condition in Equation 11 by M_{ji} . Then, we substitute for the general equilibrium object, Θ_j , to derive the following simplified expression:

$$(1 - \beta) w_j L_j M_{ij} \mathbb{E} \left[\chi_i \left(\sum_{i=1}^I \chi_i M_{ij} \right)^{-1} \right] = \frac{w_i \tau_{ij}}{z_i} M_{ij} \quad \forall i \in I.$$

This system of I equations in I unknowns defines a nonlinear complementarity problem for which efficient numerical optimization routines exist.⁸ Finally, we approximate the high-dimensional expectation by using simulations, effectively solving the following system of equations for each region:⁹

$$(1 - \beta) w_j L_j M_{ij} \frac{1}{S} \sum_{s=1}^S \left[\chi_i^{(s)} \left(\sum_{i=1}^I \chi_i^{(s)} M_{ij} \right)^{-1} \right] = \frac{w_i \tau_{ij}}{z_i} M_{ij} \quad \forall i \in I.$$

The procedure described above yields a solution to the firms' sourcing problem given a vector of wages, $\{w_i\}_{i=1}^I$. To find the equilibrium wages, we manipulate the trade balance and the optimal total intermediates expenditure conditions to derive the following

⁷There are more than 600 districts in India, but we group small contiguous districts to create 271 super-districts. We implement our model for the 271 super-districts, so that involves computing expectations over $2^{271} \approx 10^{82}$ states of the world.

⁸We solve this problem using the optimizer `PATH` implemented on `Julia` through the optimization modeling language `JuMP` (see, respectively, Ferris and Munson 1999, Bezanson et al. 2017 and Lubin et al. 2023).

⁹In our estimation procedure and in the computation of counterfactuals, we use 10,000 simulations.

equilibrium system,

$$w_j L_j = \sum_i w_i L_i s_{ji}(\{w_i\}_{i=1}^I) \quad ; \quad s_{ji}(\{w_i\}_{i=1}^I) = \frac{\frac{w_j \tau_{ji}}{z_j} M_{ji}(\{w_i\}_{i=1}^I)}{\sum_\ell \frac{w_\ell \tau_{\ell i}}{z_j} M_{\ell i}(\{w_i\}_{i=1}^I)} \quad \forall j \in I,$$

where crucially, the matrix of sourcing shares defined by $\left\{s_{ji}(\{w_i\}_{i=1}^I)\right\}_{i=1, j=1}^I$ is a function of the vector of wages and the parameters of the model. The solution to the system of equilibrium conditions above finds the equilibrium wages conditional on a vector of probabilities, $\{\rho_i\}_{i=1}^I$. We describe how we calibrate these probabilities in the next subsection.

4.2 Calibration

We group the 600 districts in India into 271 super-districts by grouping contiguous low-population districts.¹⁰ We calibrate our model to these 271 districts. To calibrate the model for India as a whole, we complement our transaction data with the Annual Survey of Industries (ASI), which is a nationally representative survey of manufacturing plants in India with more than ten employees. We primarily use the wave of 2006-07 since it is the latest year for which the ASI has publicly available data at the district level.

We need to calibrate the following parameters and moments: the demand elasticity (σ), the input disruption due to the shock (χ_j), labor endowments by district (L_i), regional productivities (ϕ_i), the labor share in the production function (β), iceberg trade costs (τ_{ij}), and flood probabilities (ρ_i).

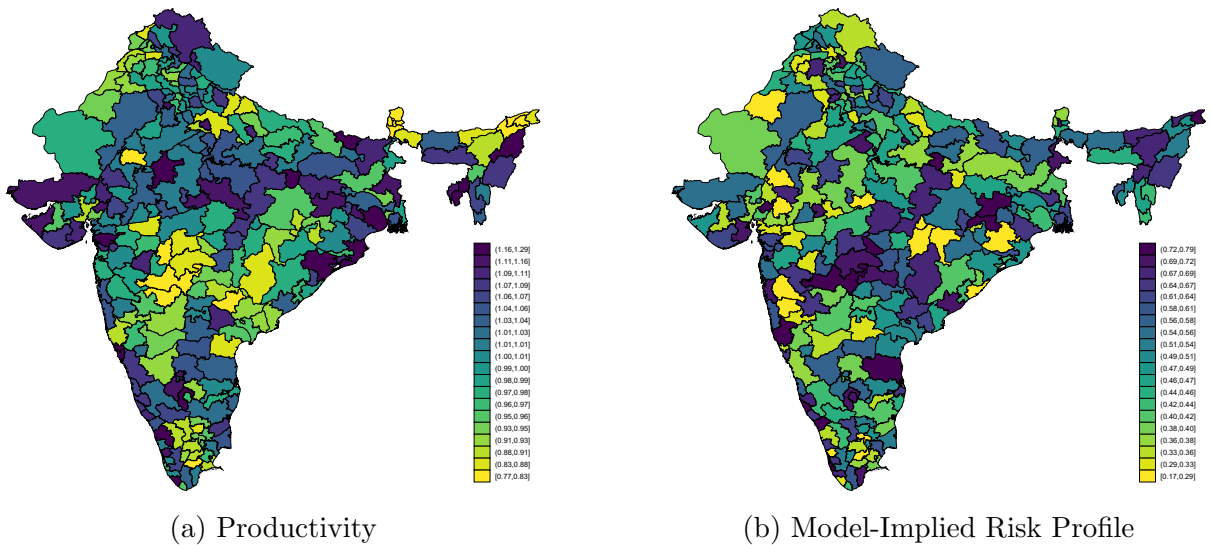

First, we set the demand elasticity $\sigma = 2$ following [Boehm et al. \(2023\)](#) and choose the input disruption parameter χ_j to match the drop of 0.77 log points in buyer purchases as supplier exposure goes from 0 to 1, as estimated in our event study ([Figure 5](#)). Second, we use the ASI to obtain employment by district, which is our labor endowments L_i .

To estimate productivities by district, ϕ_i , and the labor share β , we follow the literature on production function estimation and use the [Akerberg, Caves, and Frazer \(2015\)](#) approach (henceforth ACF). This approach requires lagged values of labor and materials as instruments, and we need a panel of firms. However, the public version of the ASI is a cross-section of plants which prevents constructing a firm-level panel. As a solution, we use the waves for 2004-05, 2005-06, and 2006-07 to construct a synthetic panel at the industry-district level. We then treat each industry-district pair as a “firm” for the purposes of estimation.

¹⁰We aggregate districts with fewer than 10000 manufacturing workers to a single district within a state, or merge them to neighboring larger districts in their own state. We present results with all districts in [Appendix C](#).

We implement the ACF procedure to estimate the production function parameters and the productivities. We use revenues as the dependent variable and labor, materials, and capital as the production function inputs. The estimation process yields coherent estimates for the inputs that add up to less than one as expected. Once we back out the ACF productivity for each industry-district pair, we aggregate at the district level by using weights based on the relative importance of each industry in each district. In the few cases where productivity cannot be estimated due to missing data for smaller districts, we assign those regions the average productivity of their closest neighbors. Panel A of Figure 18 illustrates the estimated variation in district-level productivities. From the ACF procedure we also get the corresponding coefficients for labor, materials, and capital. The results are shown in the left panel of Table 3, where the materials share is 0.81, the labor share 0.08, and the capital share 0.17. We compute the labor share as $\beta = 1 - 0.81 = 0.19$. Since we do not have capital in the model, we think of the labor share as the share of capital-augmented labor, so we include both capital and wage expenses into the calculations.

Figure 18: Estimated productivities and risk probabilities

Note. In this figure we plot the estimated district-level productivities (left panel) and the model-implied district-level shock probabilities (right panel). Productivities are estimated using the ACF procedure as described in the text. Shock probabilities are obtained by matching model-implied sourcing shares to the data as described in the text. The scales are shown to the right of each figure.

The iceberg trade costs τ_{ij} are estimated using our transaction data. Our data is only available if one node of the transaction lies in one particular state, but we need to back out trade costs for each bilateral pair of districts throughout India. To address this, we proceed in two steps. First, we use our transaction data, focus on firms in our state that sell their goods, and aggregate the data at the seller-buyer-time level. We then estimate

Equation 23.

$$\log(p_{s,b,t,q}) = \gamma_1 \log(\text{distance from } s \text{ to } b)_{s,b} + \gamma_2 \mathbb{1}(b \text{ in same state as } s)_{s,b} + \gamma_{s,q,t} + \epsilon_{s,b,t,q}, \quad (23)$$

where $p_{s,b,t,q}$ is the price charged by seller s to buyer b for product q at time t . For each buyer-supplier pair we compute the log distance between them as reported in our transaction data. We also include a dummy variable on whether the buyer (b) is in our state. The coefficient on distance captures how prices charged change as distance increases. Importantly, we add seller-product-time fixed effects, so effectively, the coefficients γ_1 and γ_2 are being identified by sellers that sell the same product to multiple buyers in a given time period. Since we are doing this within seller-product-time, the estimates are not driven by firm-level shocks such as productivity that might also affect prices. The results of this regression can be found in the right panel of Table 3.

Table 3: Estimation results

Panel A: Production Function Estimation		Panel B: Trade Costs Estimation	
	log(Sales)		log(Price _{s,b,t,q})
log(Materials)	0.81*** (0.076)	log(distance from s to b)	0.0174*** (0.0001)
log(Workers)	0.17*** (0.061)	$\mathbb{1}(b \text{ in same state as } s)$	-0.086*** (0.0001)
log(Fixed Capital)	0.08 (0.063)		
Number of Observations	9128	Number of Observations	65,477,898

Note. *** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$ Panel A presents the results of the production function estimation using the ACF procedure. The reported coefficients are for log materials, log number of workers, and log fixed capital as calculated from the ASI. Panel B presents the results for the trade costs estimation using our transaction data. The outcome is the log price charged by a seller in our state (s), for a given product (q), to a buyer (b) in a given month-year period (t). The main regressors are log distance from buyer to seller and a dummy that takes the value of 1 if the buyer is in the same state as the seller. We control for seller-product-time fixed effects.

Second, we use the estimated coefficient to predict trade costs for the rest of India. We compute bilateral distances between the centroid of each district and use those distances to predict trade costs between regions using the estimated coefficients $\hat{\gamma}_1$ and $\hat{\gamma}_2$. We assume that the border effect estimated through coefficient $\hat{\gamma}_2$ is the same for all states.

Shock probabilities. Our model implies that bilateral sourcing shares are pinned down by district fundamentals like productivities and labor force, and bilateral trade costs, in addition to the vector of district-level shock probabilities. Therefore, we can obtain the vector of shock probabilities ρ_i by minimizing the distance between the observed sourcing shares in the data with those implied by the model. The intuition of the exercise is as

follows: conditional on the rest of the parameters and moments of the model, we pick the shock probabilities of each district to match exactly the observed share of purchases from every district in our state to each other district in India. The underlying assumption is that anything that is not captured by the district-level productivities and trade costs is part of the risk of the district. Of course, in practice, such residuals do not only include flooding risk, but also many other risk components. However, in Figure 19, we show that our estimated probabilities are significantly correlated with observables related to historical flood risk as well as projected future flood risk, such as average rainfall, coastal flooding, and riverine flooding. It is worth noting that, in the case of riverine flooding, the projected flooding in 2050 is more correlated with the probabilities than the historical values. This is consistent with agents in our model considering not only realized but also potential shocks when making production decisions.

In Table 4, we run pairwise regressions of the model probabilities on the climate variables as well as other variables that could also be related to risk. Interestingly, besides the climate variables, most other variables are not significantly correlated with the risk probabilities. We also consider average temperature, court congestion, terrain elevation and ruggedness, and nightlights luminosity as alternative measures. In Appendix Table A2, we present the full regression of probabilities on all observables. Finally, in Figure A7, we show that these probabilities are not correlated with either productivities, nor the average distance to the state of our study.

Table 4: Pairwise regressions between model probabilities and observables

	Log daily rainfall (historical)	Log daily rainfall (projected 2050)	Log coastal flooding (historical)	Log coastal flooding (projected)	Log riverine flooding (historical)	Log riverine flooding (projected 2050)
Coefficient	0.0405*** (0.0135)	0.0145* (0.00840)	0.316* (0.161)	0.237** (0.120)	0.0778 (0.0654)	0.166*** (0.0474)
N obs	271	271	271	271	271	271
R2	0.032	0.011	0.014	0.014	0.005	0.044

	Log avg temperature (historical)	Log avg temperature (projected 2050)	Log avg nightlights luminosity	Log avg elevation	Log avg ruggedness	Log avg court congestion
Coefficient	-0.0382 (0.0432)	-0.0566 (0.0409)	0.00310 (0.00958)	-0.0138*** (0.00525)	-0.00386 (0.0110)	-0.0141 (0.0507)
N obs	271	271	271	271	271	271
R2	0.003	0.007	0.000	0.025	0.000	0.000

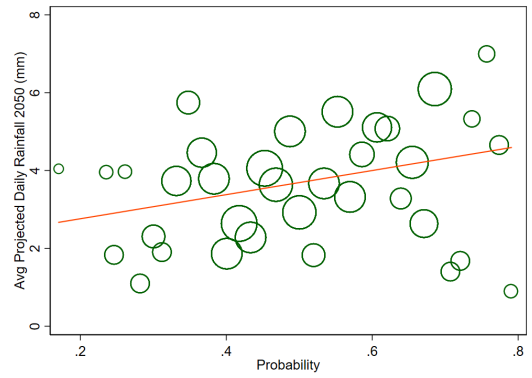

Note. *** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$ We run pairwise regressions of the model probabilities on observables. Each of the columns in the table shows the regression coefficient of the different variables. Probabilities and observables are logged. A more detailed definition of each of the variables can be found in Appendix C.2.

Notice that this exercise requires solving jointly for the vector of district-level risk that minimizes the gap between model-implied sourcing shares and data, as all bilateral sourcing shares are equilibrium objects that depend on the fundamentals and risk of all other districts. Further, we cannot exactly match all bilateral sourcing shares in the data, as we choose a single shock probability for each district, but we observe multiple sourcing

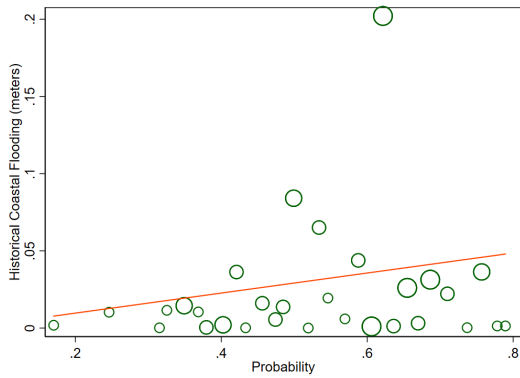

Figure 19: Model probabilities and observables

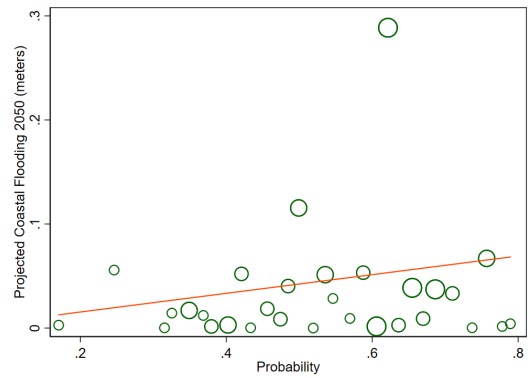

(a) Daily Rainfall - Historical

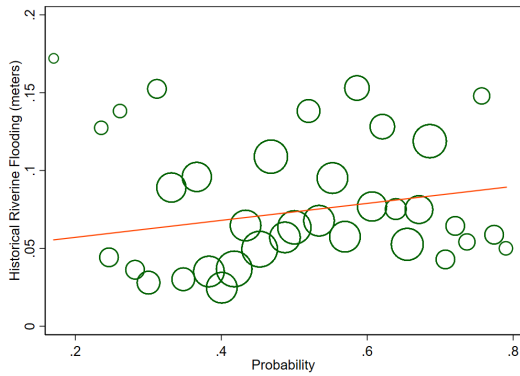

(b) Daily Rainfall - Projected 2050

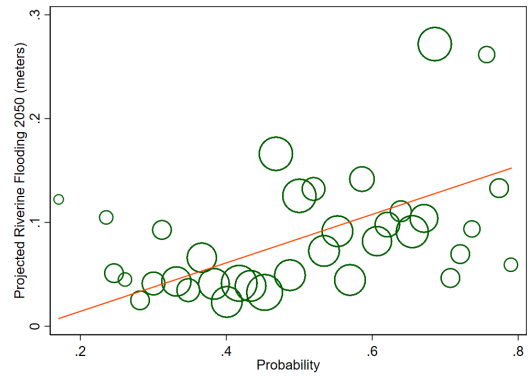

(c) Coastal Flooding - Historical

(d) Coastal Flooding - Projected 2050

(e) Riverine Flooding - Historical

(f) Riverine Flooding - Projected 2050

Note. In this figure, we plot the estimated probabilities against climate observables. In Figure 19a, we correlate the probabilities with the average daily rainfall in 2019 (historical). In Figure 19b, we use the rainfall projections for year 2050. Figures 19c and 19d use the historical and projected coastal flooding, while Figures 19e and 19f correlate the probabilities with historical and projected riverine flooding, respectively. A more detailed definition of each of the variables can be found in Appendix C.2.

shares for that district from all districts in our “state.” We therefore set up a Minimum Distance Estimator, which aims to match the average sourcing shares for each origin dis-

trict observed across all destination districts in our data. In practice, we also are able to match all the bilateral sourcing shares in the data well, as Figure 20 shows. As external validation, the right panel of Figure 20 shows that our model also matches the data on sales shares well, which are untargeted moments.¹¹

Table 5 summarizes our model calibration.

Table 5: Calibrated moments

Parameter	Source
L_i : Labor endowments	Annual Survey of Industries (ASI), 2019-20
ϕ_i : Region productivities	Akerberg et al. (2015) estimation (ASI, 2017-2019)
τ_{ij} : Iceberg trade costs	Regression of within firm-product price on distance between buyer and seller (Transaction data)
ρ_i : Flood probabilities	Model inversion using sourcing shares across districts (Transaction data)
χ_i : Flood shock	Match drop in buyer purchases from event study (Transaction data)
β : Labor share	0.17: Expenditure in labor and capital to total sales (ASI, 2017-2019)
σ : Demand elasticity	2: Based on (Boehm et al., 2023)

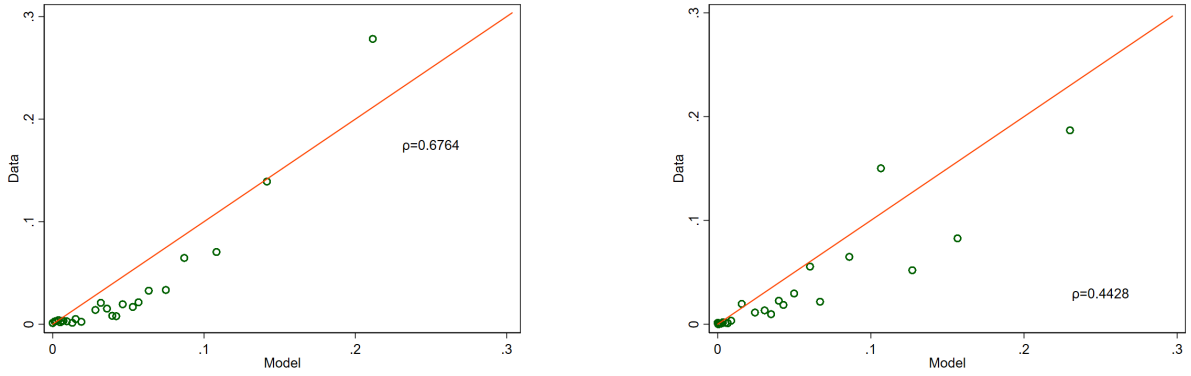

4.3 Quantitative Results

We begin by showing that the model delivers a strong negative relationship between shock probabilities and relative nominal wages (and real wages) in the cross-section. Figure 21 shows that both nominal and real wages are negatively correlated with shock probabilities, as we would expect. In Figure A8, we also show that the price index and the variance in real wages are negatively correlated with the shock probabilities.

Probabilities and sourcing shares. To illustrate the rich heterogeneity in bilateral sourcing patterns in the quantitative model, we show the sourcing choices of two districts in Figure 22. The left panel illustrates the sourcing patterns of New Delhi, a relatively low risk district. The right panel shows the sourcing shares chosen by Kolkata, a high-risk

¹¹While our estimated probabilities might seem high, as discussed above, they capture several sources of risk. Further, available evidence from Indian businesses suggests that supply chain disruptions are a key concern. For instance, PwC’s 26th Annual Global CEO Survey in late 2022 found that 50% of India CEOs were concerned about supply chain disruptions (<https://www.pwc.in/assets/pdfs/research-insights-hub/immersive-outlook-3/paradigm-shift-in-supply-chain-management.pdf>).

Figure 20: Sourcing shares: Model vs. Data

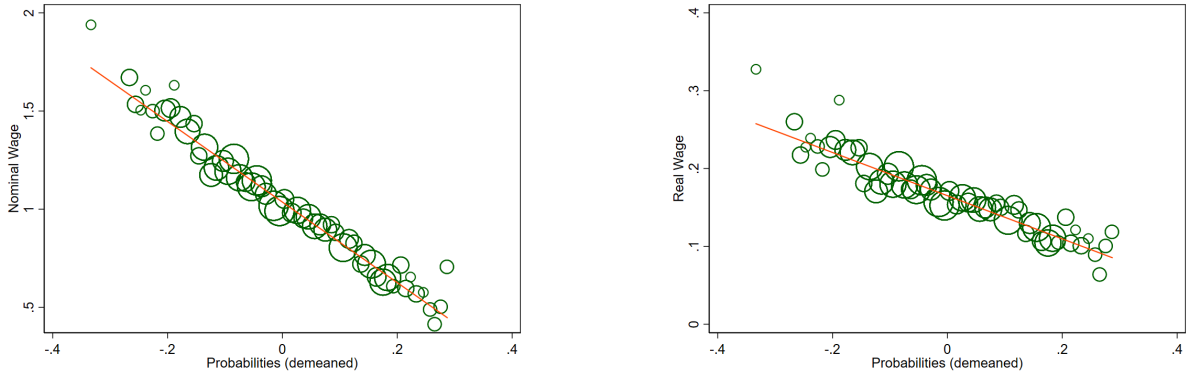

(a) Input Shares

(b) Output Shares

Note. In this figure, we plot the sourcing shares in the data against the model. The red line is a 45-degree line. In the left panel we plot the input sourcing shares. We target average sourcing probabilities from our state’s districts to the rest of the districts, but we do not force anything to match the particular sourcing shares of each district. The left panel plots each individual district’s input shares. The right panel shows sales shares, which are entirely untargeted.

Figure 21: Shock probabilities and wages

(a) Nominal Wages

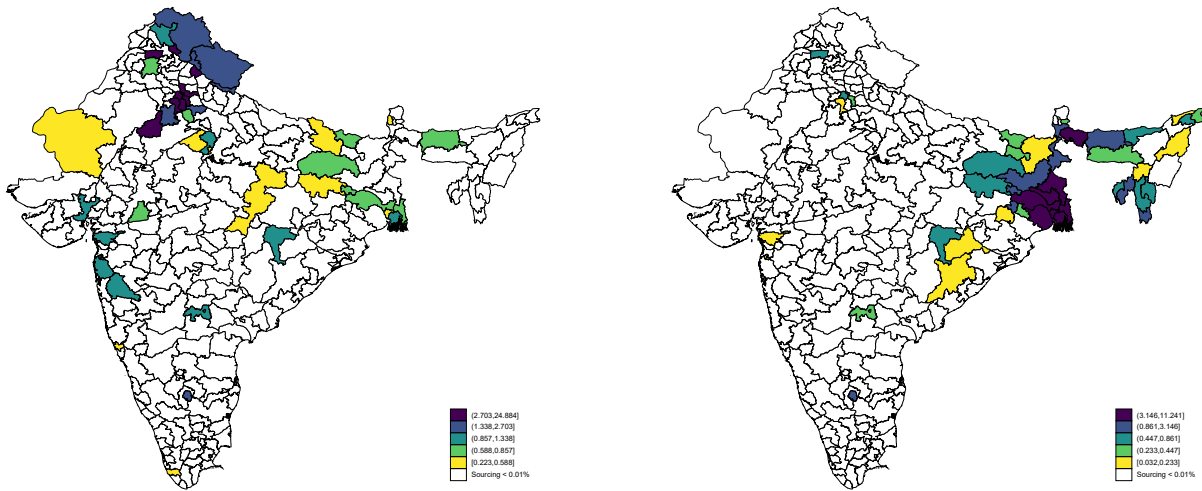

(b) Real Wages

Note. In this figure, we plot model-derived nominal (left panel) and real wages (right panel) against the estimated shock probabilities. Figure A8 further plots the price index and the variance in real wages against the shock probabilities.

district. In both districts, firms diversify, but sourcing strategies depend on geography – they source more from geographically closer areas. Diversification also depends on the risk profile of the origin district – for Kolkata, the model implies the district’s firms choose more interdistrict sourcing to mitigate risk. In fact, while New Delhi’s highest sourcing share is own-district sourcing (nearly 25%), Kolkata’s largest sourcing shares are not own-district sourcing. In fact, own-district sourcing in Kolkata is only around 7.25%. Notice that the sourcing patterns for both districts imply several zeros (our solution algorithm permits zero sourcing shares in equilibrium, as discussed in Section 4.1). In Appendix C, we show that under free trade, the sourcing patterns for all regions are identical, and each

region sources from districts all over the country.

Figure 22: Delhi sourcing, Kolkata sourcing

Expected real wages under baseline and autarky. The comparative statics in Section 3 showed that with identical regional fundamentals, expected real wages were lower for all regions with costly trade than in autarky. To assess whether this mechanism is quantitatively relevant in the calibrated model with varying regional fundamentals and estimated trade costs, we compute the difference in expected real wages in the baseline model with the model-implied expected real wages given the same regional fundamentals and infinite trade costs.

Figure 23 illustrates the spatial variation of expected real wages in the baseline model and in the autarky counterfactual. On average, expected real wages are 5.0% higher in the baseline model than in autarky. However, 10.7% of districts have lower expected real wages. The variance of real wages is 77.6% lower in the baseline model than in autarky, validating the quantitative relevance of the main comparative statics exercises.

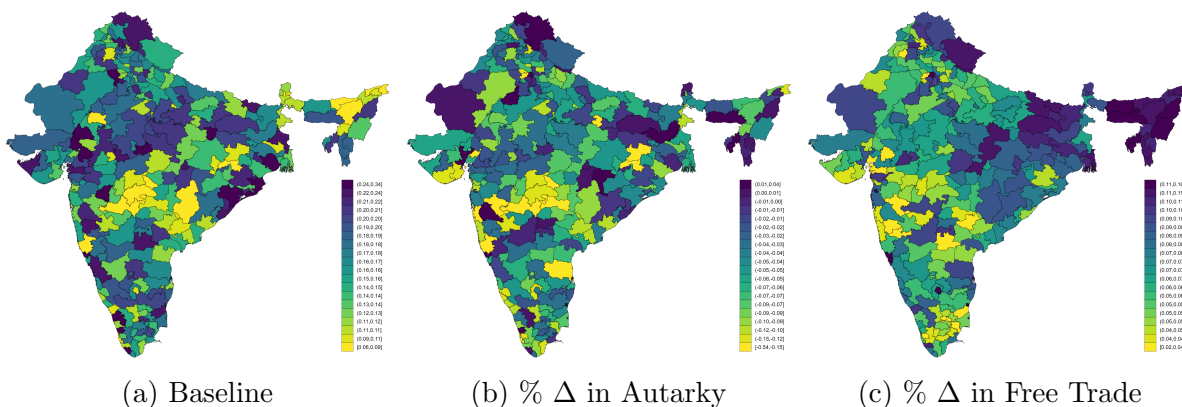

The quantification also makes clear where the deviation from the stark comparative statics result with identical fundamentals arises. The regions that see welfare gains in autarky relative to costly trade are those that have relatively lower risk and high productivity, leading to high equilibrium expected real wages in under both trade and autarky. These regions do not benefit much from diversification of their own risk, as they are lower risk. With costly trade, there are two opposing effects, Diversification by riskier districts pushes up the nominal wages in these districts, as their fundamentals make them attractive sourcing locations. On the other hand, the prices of their final goods also go up as their “own” input costs increase through the wage effects. They also diversify and source relatively higher cost traded inputs. For these regions, the increase in final goods prices more than offsets the nominal wage increase, and they see a decline in expected real wages

under costly trade.

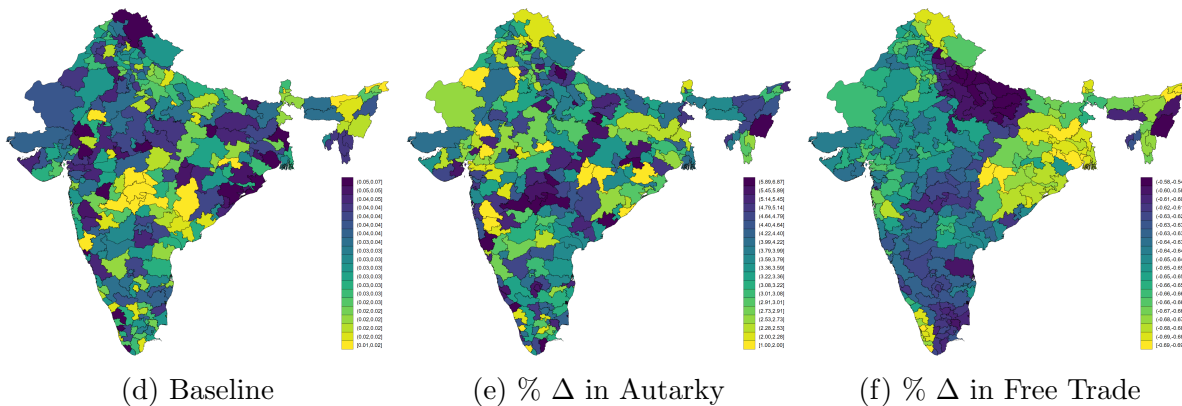

Expected real wages under baseline and free trade. In contrast, Figure 23 shows that expected real wages are higher for many regions under a free trade counterfactual. To implement free trade in our quantitative exercise, we set the iceberg trade costs to 1 between all districts. Under free trade, expected real wages are on average 8.0% higher than in the baseline, whereas the variance of real wages is 64.4% lower.

Figure 23: Quantitative results

Panel A: Expected real wages

Panel B: Variance of real wages

Note. This figure shows expected real wages (Panel A) and their variance (Panel B). The left column shows expected real wages and their variance in the baseline calibrated model. In the middle and right columns, the figure shows the percentage changes in expected real wages under the autarky and the free trade counterfactuals relative to the baseline scenario. In the bottom panel, the middle and right figures show the percentage changes in the variance of real wages under the autarky and the free trade counterfactuals relative to the baseline scenario.

Inventories. In Appendix B.3 we develop an extension of our model to a setting with intermediate input inventories. While we lack detailed inventory data to quantify this extension, we show that the model can qualitatively generate a pattern similar to that in

Figure 5, with a larger decline in inputs than in sales following a shock. The extension makes clear the ability to hold inventories does not change a firm’s diversification motives ex-ante, as the firm’s expected profit function remains convex in input orders. However, existing inventories do shift the level of inputs available within a period for production, which mitigates the short-run effects of a shock on output should one occur.

4.4 Climate Change Counterfactuals

While the previous section explored several counterfactuals, such as autarky or free trade, we next study the implications of increasing climate risk in our model. We estimate the share of our model-implied shock probabilities that can be explained by climate-risk-related variables such as rainfall or flooding events. Through the lens of our model, these probabilities capture the risk firms assign to each district. However, as discussed above, the risk associated with each region can be due to climate risk, but also other regional characteristics such as infrastructure or governance. In this section, to highlight the implications of changing climate risk, we hold all other sources of risk constant and double the climate risk of each region relative to the baseline.

We proceed as follows: First, we regress the inverse logit transformation of our probabilities on the historical measures of rainfall, coastal flooding, and riverine flooding presented in Figure 4. Second, we use the estimated coefficients to predict the value of the probabilities in 2050 using the projected values for rainfall, coastal flooding, and riverine flooding, also presented in Figure 4. This method yields how the probabilities would change if climate variables evolve as predicted.

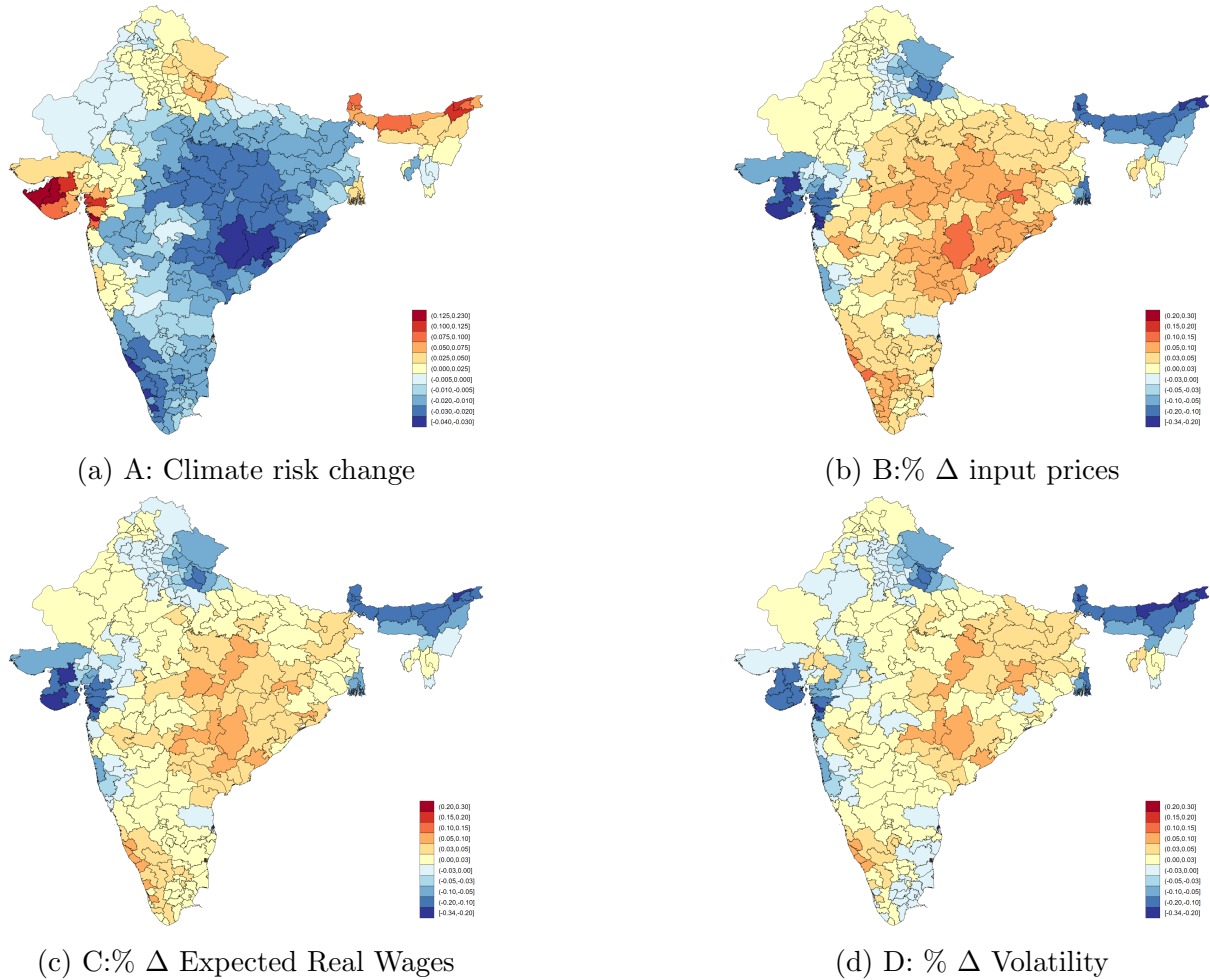

Panel A of Figure 24 illustrates how these probabilities change across space in our main counterfactual. As the figure makes clear, there is wide variation in the changes in climate risk, with the northeast and parts of the west coast seeing large increases in risk, while the central part of the country sees decreases in risk. On average, risk increases by 0.38 percentage points. Panel B illustrates the change in supplier input prices across the country in this counterfactual. There is less variation in the supplier input price changes, but the regions that see the highest climate risk increases see decreases in the input prices their intermediate producers offer.¹²

Panel C illustrates changes in expected real wages. The riskiest regions see the largest declines in expected real wages, while regions that get safer see increases. On average, there is an 1% decline in expected real wages, and an 1.14% decline in their volatility. 62.4% of districts see expected real wage gains, however, reflecting that the majority of districts see lower climate risk in the counterfactual.

¹²Recall input prices $p_i = \frac{w_i}{z_i}$. Effectively, the nominal wages in risky regions are decreasing, although by less than the increase in their risk due to general equilibrium effects of sourcing diversification.

Climate change has implications for spatial inequality. It will adversely affect regions in the North East, which already have low wages. Climate risk will not only subject them to increased flooding, but also a decrease in real wages as supply chains become less reliant on this region. In Figures A9 and A10, we show results where only the probability of floods or of precipitation increases. Table 6 summarizes the quantitative results across all counterfactuals.

Figure 24: Counterfactuals: Climate Risk Increase

Note. In this figure, we plot the change in probabilities of climate risk (panel A), the change in district input prices (panel B) the change in expected real wages (panel C) and the change in the volatility of real wages (Panel D) as climate risk increases as described in Section 4.4.

5 Conclusion

Climate risk is an increasingly important concern worldwide, with large projected economic impacts. Adaptation of firm supply chains to perceived climate risk is a crucial channel through which economies might adjust to climate risk. Such adaptation has implications for the spatial concentration of economic activity and regional income. Re-

Table 6: Model Counterfactuals: Summary

Counterfactual	Expected Real Wages		Real Wage Volatility		% districts Real wage declines
	Avg. change	Range	Avg. change	Range	
<u>Baseline risk</u>					
Autarky	-4.46%	6.01 p.p	348.57%	187.12 p.p	89.30%
Free Trade	8.05%	3.72 p.p	-64.37%	3.58 p.p	0.00%
<u>Alternative risk</u>					
Climate change	-1.00%	4.65 p.p	-1.14%	3.76 p.p	37.6%
Only Rainfall Risk	-0.60%	4.1 p.p	-0.72%	3.28 p.p	38.3%
Only Flood Risk	-0.40%	0.25 p.p	-0.46%	0.28 p.p	55.7%

Note. This table shows statistics of the distribution of percentage changes between the baseline scenario with current climate risk and costly trade and other scenarios. Range refers to the interquartile range.

gions that are low-risk but less productive might see increases in their real wages as firms diversify their supply chains.

This paper provides empirical evidence suggesting firm supply chains are structured taking climate risk into account. Our new model of firm supply chain decisions under risk incorporates key patterns we see in the data: firms source the same inputs from multiple locations and seek drier regions to source inputs even when they are farther away. The model results suggest that, on the one hand, input sourcing decisions mitigate climate risk as firms diversify their sources. Yet, on the other hand, they amplify the distributional effects, as regions that face adverse climate shocks will also suffer lower real wages.

Our quantification exercise infers that the impact of climate risk on firm sourcing delivers important implications for economic activity across space. In particular, expected real wages are higher for regions that are less risky. Further, for some regions expected real wages decrease under costly trade compared to autarky, as firms diversify their climate exposure by sourcing inputs from less productive and more costly producers. However, the volatility of real wages is unambiguously lower with the possibility of diversification through supply chains.

A Details on the Firm-to-Firm Data

We illustrate a stylized example of our establishment-level networks data in Figure A1. As the diagram shows, we observe all transactions where one node of the transaction is within the state. This includes all transactions between establishments within the state (the yellow lines), any inflows from or outflows to the rest of the country (the blue lines), and all international imports and exports (the green lines).

Figure A1: Stylized Example of Establishment-Level Network

Notes: Stylized example of establishment-level data. The upper half represents the country, and the upper left quadrant represents the state in question. The data includes all transactions within the state, and all transactions where one node of the transaction (either buyer or seller) is in the state.

The data report value and quantity of traded items, so we can construct unit values. To do this, we aggregate values and quantities at the four-digit HSN/month/transaction level, and then construct implied unit values. We can then collapse the data at the 4-digit HSN/month level to construct average unit values, the number of transactions between each seller and buyer pair, and total value of the goods transacted. This is the foundation of the firm-to-firm dataset we use in the analysis. Additionally, we can aggregate these data to the buyer level, which we use in our reduced-form section. Table A1 summarizes our primary variables of interest using this dataset.

Table A1: Summary Statistics for Main Variables

Outcome	Mean	p25	p50	p75
Separation Rate (%)	30.9	0	16.67	52.78
Entry Rate (%)	74.06	0	50	106.67
Net Separations (%)	-43.12	-70	0	0
Real Input Value (log)	14.91	12.48	14.55	16.96
Real Sales (log)	16.33	13.57	16.05	18.66
Avg. Supplier Size (millions of rupees)	106.42	9.65	34.04	127.49
Avg. Supplier Outdegree	43.04	3.3	10.97	31.99
Share Purch. Lgst. Supplier (%)	52.39	31.06	47.84	71.82
Number Products	12.05	3	7	14
Share Purch. Diff. Prod. (%)	60.19	21.25	72.78	97.81
Supply Chain Depth	32.32	28.15	31.46	36.35
Number Suppliers	12.35	3	7	14
Avg. Distance (km)	486.71	97.13	251.65	712.75
Share Purch. Non-Home State (%)	38.54	0	24.42	78.48

Note. We calculate summary statistics for key outcomes to describe the network. Summary statistics calculated in December 2019-February 2020. Number of firms included in calculations: 136,562.

B Theory Appendix

B.1 Proofs

Proposition 1: Proof. Since the cost of materials is linear in M_{ij} and the constraints are conventional (linear) non-negativity constraints, it suffices to show that the expected operating profits function $\mathbb{E}_{\chi}(\pi(\mathbf{M}; \chi))$ is concave in the vector \mathbf{M} . The expectation operator preserves the concavity of $\pi(\mathbf{M}; \chi)$ which is the only thing required to prove. The concavity of ex-post profits, $\pi(\mathbf{M}; \chi)$, follows from the parametric restriction, $\frac{(1-\beta)(\sigma-1)}{\beta+\sigma(1-\beta)} < 1$. ■

Lemma 1: Proof. Notice that, conditional on some state of the world, χ , ex-post aggregate profits are given by,

$$\int_{\omega \in [0,1]} \pi_i(\omega; \chi) d\omega = \int_{\omega \in [0,1]} \left(p_i(\omega; \chi) q_i(\omega; \chi) - w_i \ell_i(\omega; \chi) - \sum_j p_{ji}^I M_{ji}(\omega) \right) d\omega.$$

Using the assumption of a unit mass of homogenous firms in a region, ex-post aggregate profits are then

$$\pi_i(\chi) = p_i(\chi) q_i(\chi) - w_i(\chi) \bar{L}_i - \sum_j p_{ji}^I M_{ji}.$$

where $p_i(\chi) q_i(\chi)$ corresponds to aggregate revenues from the final goods sector, $w_i(\chi) \bar{L}_i$ are payments to residual labor, and $\sum_j p_{ji}^I M_{ji}$ is total expenditure on intermediate inputs. As final goods firms are monopolistically competitive and the final goods aggregator is

CES, standard algebra shows that profits are a constant fraction of revenues:

$$\pi_i(\boldsymbol{\chi}) = \frac{p_i(\boldsymbol{\chi})q_i(\boldsymbol{\chi})}{\sigma}.$$

The budget constraint implies equilibrium revenues are simply labor income plus profits $p_i(\boldsymbol{\chi})q_i(\boldsymbol{\chi}) = Y_i(\boldsymbol{\chi}) = w_i(\boldsymbol{\chi})L_i + \pi_i(\boldsymbol{\chi})$. Combining these expressions, we can show that

$$\pi_i(\boldsymbol{\chi}) = \frac{w_i(\boldsymbol{\chi})L_i}{\sigma - 1} \quad ; \quad Y_i(\boldsymbol{\chi}) = \frac{\sigma}{\sigma - 1}w_i(\boldsymbol{\chi})L_i$$

This further implies that aggregate costs of firms are $\frac{(\sigma-1)}{\sigma}Y_i$ and aggregate expenditure on materials is then $\sum_j p_{ij}^I M_{ij} = \frac{(1-\beta)(\sigma-1)}{\sigma}Y_i$. ■

Lemma 2: Proof. We prove that wages in each location i , w_i , are deterministic by showing that labor market clearing must occur at the time of producing intermediates.

By backward induction, after intermediate inputs have been produced, final goods producers in each region face an inelastic residual labor supply equal to \bar{L}_i . Aggregate labor demand in each region is given by,

$$L_i^D(\boldsymbol{\chi}) = \left[\frac{Y_i(\boldsymbol{\chi})}{\phi_i \left(\sum_{j \in I} \chi_j M_{ij} \right)^{1-\beta} p_i(\boldsymbol{\chi})} \right]^{\frac{1}{\beta}},$$

where final goods' prices can be written as

$$p_i(\boldsymbol{\chi}) = \left[\frac{\beta(\sigma - 1)}{\sigma} \right]^{-\beta} \phi_i^{-1} \left(\sum_{j \in I} \chi_j M_{ij} \right)^{-(1-\beta)} w_i(\boldsymbol{\chi})^\beta Y_i(\boldsymbol{\chi})^{1-\beta}.$$

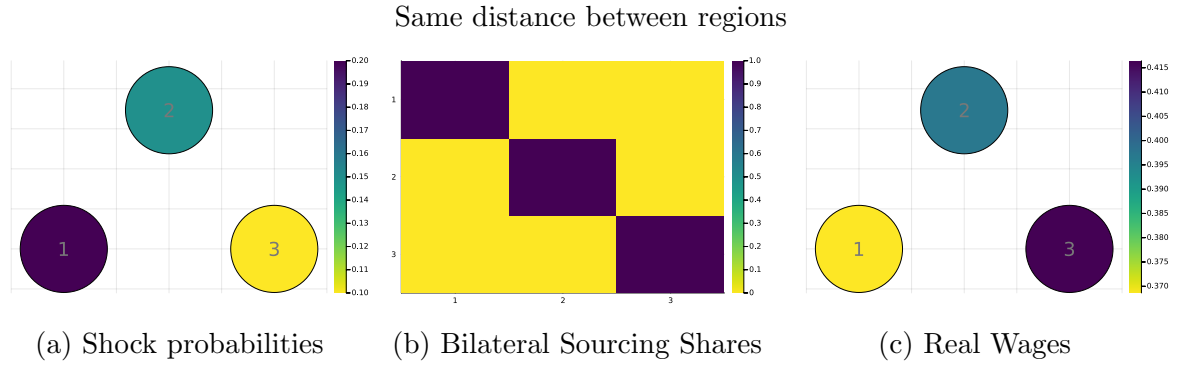

If we plug the expression for prices, in the aggregate labor demand equation, and simplify we get that,

$$L_i^D(\boldsymbol{\chi}) = \beta L_i$$

Crucially, aggregate labor demand by final goods producers does not depend on the realization of the shocks, $\boldsymbol{\chi}$. However to clear the labor market in each location the wage rate needs to be such that the residual labor supply that final goods' producers face, \bar{L}_i , is equal to their inelastic labor demand. The wage rate is set ex-ante when intermediate good production takes place and is independent of the realization of the shocks. As a corollary, this implies that the wage rate, $w_i(\boldsymbol{\chi})$, aggregate profits $\pi_i(\boldsymbol{\chi})$ and aggregate income $Y_i(\boldsymbol{\chi})$ are all deterministic. ■

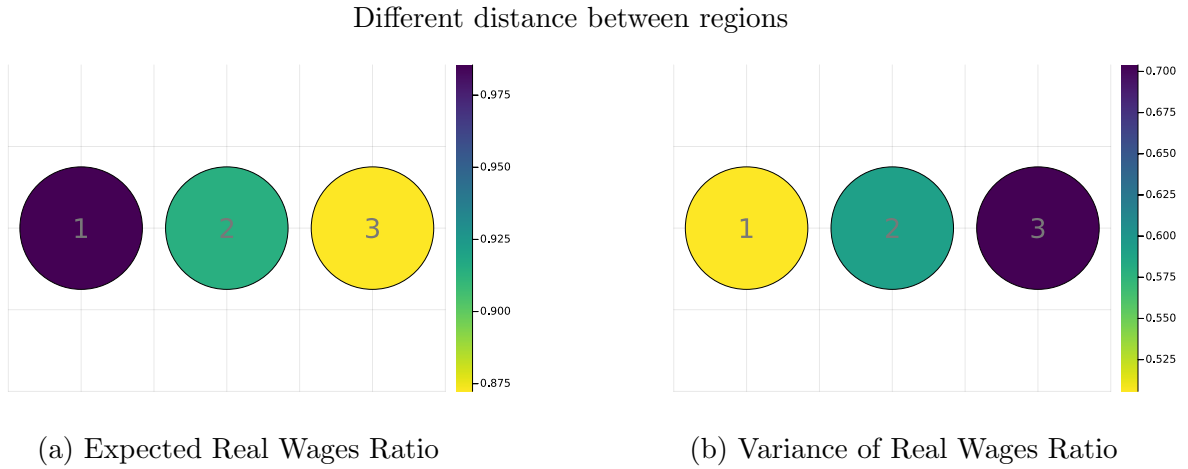

B.2 Additional Results: Comparative Statics

Figure A2: Scenario with heterogeneous risk and infinite trade costs

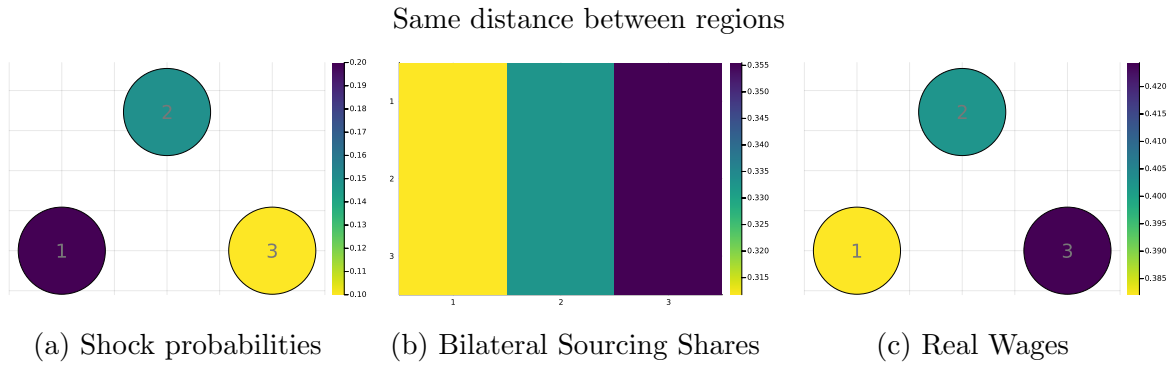

Note. This figure presents the case where trade costs are set to infinity and regions are equidistant. The figures in the left panel show the probability that each region is hit by a shock, as well as a visual representation of the geographical location of regions in space. The figures in the middle panel consist of a 3x3 input-output matrix where the buying regions are in the vertical axis and the supplying regions are in the horizontal axis. Each line represents the share of inputs purchased by a buying regions from each supplying region. The right panel present the real wages for each region. The scales are shown to the right of each figure. The case with heterogeneous distance between regions is shown in Figure 14.

Figure A3: Comparison between heterogeneous risk under costly trade and autarky

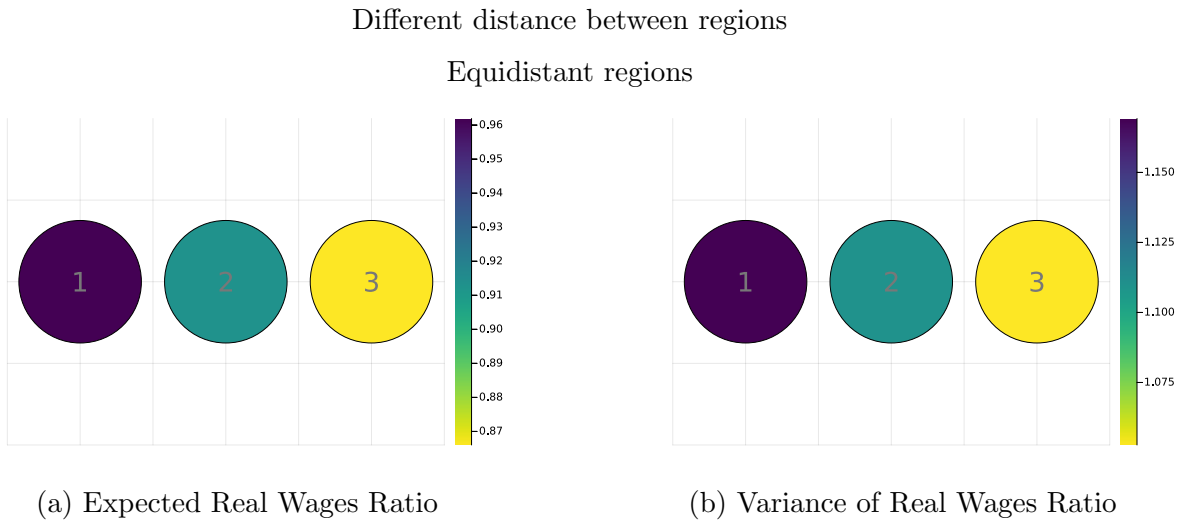

Note. In this figure we plot the expected real wages (left panel) and variance of real wages (right panel) for the scenario with heterogeneous risk and costly trade shown in Figure 12 relative to the scenario with heterogeneous risk and trade autarky shown in Figure 14. The variance of real wages is computed across potential states of the world. In this scenario, regions are equidistant from each other. The scales are shown to the right of each figure. The case with regions in a line is discussed in Figure 15.

Figure A4: Scenario with heterogeneous risk and free trade

Note. This figure presents the case where there are no trade costs. The figure in the left panel show the probability that each region is hit by a shock, as well as a visual representation of the geographical location of regions in space. The figure in the middle panel consist of a 3x3 input-output matrix where the buying regions are in the vertical axis and the supplying regions are in the horizontal axis. Each line represents the share of inputs purchased by a buying regions from each supplying region. The right panels present the real wages for each region. Here, regions are equidistant from each other. The case with heterogeneous distance is in Figure 16. The scales are shown to the right of each figure.

Figure A5: Comparison between costly and free trade

Note. In this figure we plot the expected real wages (left panel) and variance of real wages (right panel) for the scenario with heterogeneous risk and costly trade shown in Figure 12 relative to the scenario with heterogeneous risk and free trade shown in Figure 16. The variance of real wages is computed across potential states of the world. Here, regions are equidistant from each other. The case with regions on a line is shown in Figure 17. The scales are shown to the right of each figure.

B.3 Inventories

We next extend our model to allow firms to hold inventories of their material inputs. We assume inventories accumulated at t can be costlessly stored for one period and used in $t + 1$, after which they fully depreciate. The assumption of full depreciation after one period (a quarter) is made for analytical convenience, to curtail the dimension of the state space. However, this setting is sufficient to capture the main motive for firm inventory holdings, as insurance against the i.i.d shocks in this model, and to illustrate that we can qualitatively replicate the pattern in the event studies where shocked buyer output declined less than inputs. Notice that the costs of holding inventories in a country like India are likely higher than the U.S. . However, we lack detailed data on plant or firm inventory holdings to discipline the costs of storage, and so assume costless storage from one quarter to the next (over a total period of 6 months) and full depreciation after.

Timing. At the production stage, firms additionally choose the share of intermediate inputs a_t they want to use to produce in the period. A share $1 - a_t$ will then stock inventories, that will carry to the next period.

Firm problem, stage 2. In period t , and after disruptions have taken place, a firm with inventories e_{t-1} solves the following problem:

$$\mathbb{V}^{post} \left(e_{t-1}, \sum_{j \in I} \chi_{jt} M_{ijt} \right) \equiv \max_{a_t} C \left[\left(a_t \sum_{j \in I} \chi_{jt} M_{jit} + e_{t-1} \right)^{(1-\beta)(\sigma-1)} \right]^{\frac{1}{\beta+\sigma(1-\beta)}} + \delta \mathbb{V}^{ante} (e_t) \quad (24)$$

such that

$$e_t = (1 - a_t) \sum_{j \in I} \chi_{jt} M_{ijt} \quad (25)$$

$$a_t \in [0, 1] \quad (26)$$

$$\mathbb{V}^{ante} (e_{t-1}) \equiv \max_{M_{ijt} \geq 0} \mathbb{E} \left[\mathbb{V}^{post} \left(e_{t-1}, \sum_{j \in I} \chi_{jt} M_{ijt} \right) - \sum_j p_j M_{jit} \right] \quad (27)$$

Here, $\mathbb{V}^{post} (\cdot)$ is the forward looking firm's value function after shocks have materialized in period t and C is a constant. At this point, the firm holds inventories of e_{t-1} stored from the previous period, which is an additional state variable. Equation (24) is the dynamic analog of the firm's ex-ante profit maximization condition in Equation (6). Firms now

have the choice of storing inputs as inventories for period $t + 1$, with the constraint that the share of inputs stored as inventories cannot exceed 1. There are no additional storage costs, so the choice of a_t pins down e_t which are available to produce in $t + 1$ (Equation (25)). At the beginning of a period, the firms' value function is \mathbb{V}^{ante} , which is the dynamic analog of Equation (10) given the state variable, the existing inventories, e_{t-1} .

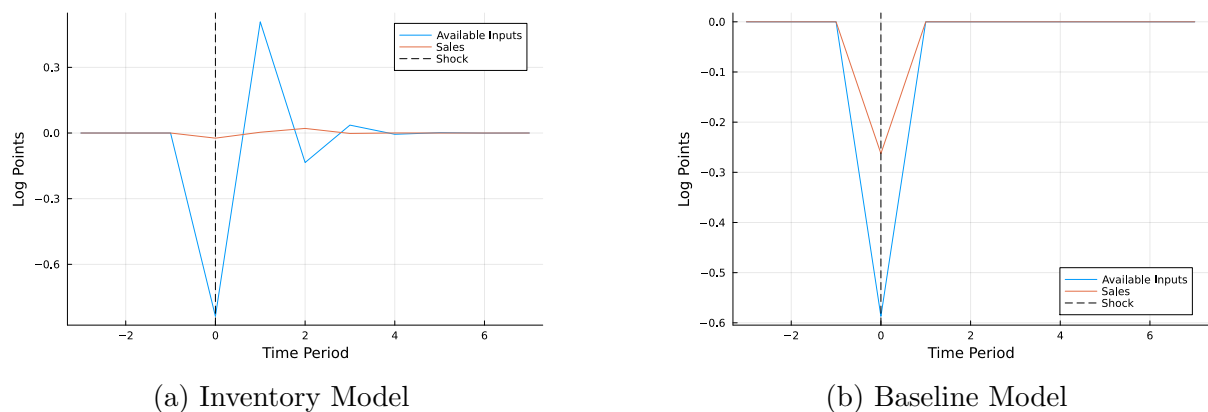

The Euler equation for a_t is:

$$\left[a_t \sum_{j \in I} \chi_{jt} M_{ijt} + e_{t-1} \right]^{\frac{(1-\beta)(\sigma-1)}{\beta+\sigma(1-\beta)} - 1} = \delta \mathbb{E} \left(\left[a_{t+1} \sum_{j \in I} \chi_{jt+1} M_{ijt+1} + e_t \right]^{\frac{(1-\beta)(\sigma-1)}{\beta+\sigma(1-\beta)} - 1} \right). \quad (28)$$

In other words, a firm in stage 2 chooses inventories for stage 1 of the next period in such a way that it equates the marginal return of materials today with the expected marginal return of those materials tomorrow.

Calibration. We simulate this model in partial equilibrium. Under the assumption of complete discounting ($\delta = 0$) the model collapses to our baseline model. We assume a firm in i 's input orders from some location j face an unanticipated shock at $t = 0$ with a magnitude such that available inputs decline by 75% to match the event studies in Section 2.3. Figure A6 illustrates the time path of firm input purchases and sales following the shock, with the inventory mechanism in Panel A and the baseline model with no inventories in Panel B.

Figure A6: Inventory Model: Sales and Inputs

Note. In this figure, we show the responses of firm sales and input purchases in the model with inventories (left panel) and in the baseline model (right panel).

As is clear from Panel A of Figure A6, adding in the inventory holding mechanism helps firms further smooth sales when they experience a shock to inputs. In fact, the simple

framework here matches the qualitative patterns in the event studies well – inputs decline and then overshoot in the recovery, as firms reaccumulate inventories. Sales in contrast experience a very small decline. Panel B illustrates the responses in our baseline model. Here, for the same decline inputs, sales experience a larger decline relative to Panel A. However, sales fall by less than inputs, illustrating that the diversification across sourcing locations also provides firms an additional means by which to mitigate sales declines when exposed to risk.

Conceptually, inventories and sourcing location diversification are two approaches by which firms can mitigate output volatility. In practice, the trade-off between these two approaches and their relative importance will depend on the relative costs, higher cost inputs vs the costs of inventory storage. As we lack data to discipline inventory holding costs, and the model with inventories is less tractable in general equilibrium, we focus on the sourcing location diversification. Our descriptive evidence suggests that firms are engaging in such diversification, so it is a salient mechanism in practice. Notice that in our model, even given a level of inventories in a period, firm’s expected profits remain concave in (residual) input orders, and so firms will continue to diversify across sourcing locations.

C Quantitative Appendix

C.1 Dataset construction

In Section 4.2, we use multiple sources to correlate our model implied probabilities with observables related to supply chain disruption risk. We consider four climate related measures: rainfall, coastal flooding, riverine flooding, and average temperatures. Our climate data is available for grid areas that are much more detailed than our 271 regions. In such cases, we use shape files to overlay our regions to the available maps and calculate the average measure of the climate variables within each of our regions.

Coastal and riverine flooding are taken from the World Resources Institute’s Aqueduct Floods Hazard Map. Historical flooding is defined as the present day meters of flooded areas. Projected flooding are the expected meters of increase in flooded areas expected in 2050. We use 10-year floods and the RCP 4.5 as our baseline projection.

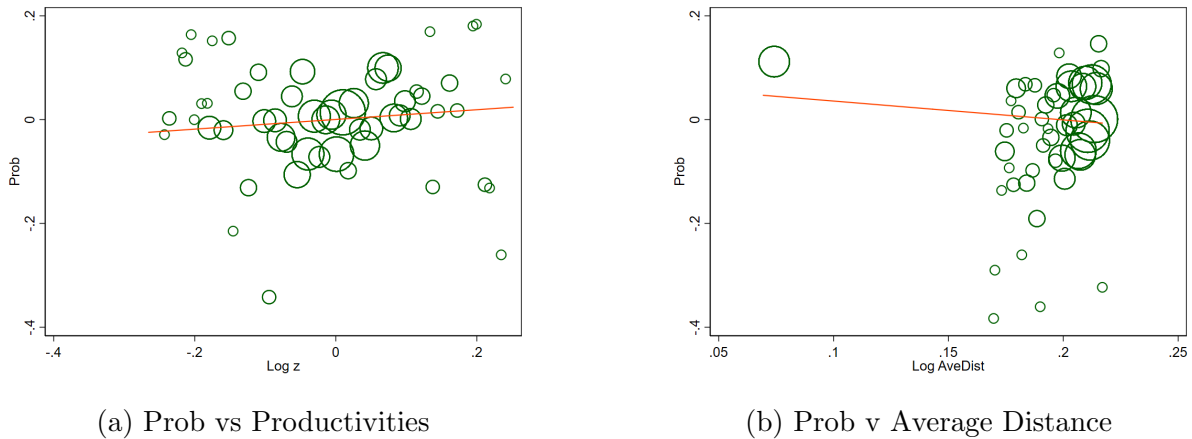

Historical and projected temperature data is taken from the IPCC WG1 Interactive Atlas. Historical temperatures are the average daily degrees centigrade in 2005 (the latest year available for historical data). Projected data for 2050 is calculated assuming a risk scenario of RCP 8.5 and using a risk model of NOAA global circulation model and the Swedish Meteorological and Hydrological Institute’s local circulation model.

Daily rainfall data is taken from the India Meteorological Department and measured in millimeters. We take the average across all days in 2019 for each district. For predicted rainfall, we first extract the average historical (measured in 2005) and predicted 2050 rainfall from the IPCC WG1 Interactive Atlas, using the same settings as for temperature. We then compute the change for each district between 2005 and 2050, and apply the implied yearly change to update the 2019 values to 2050.

The non climate variables mostly come from the Socioeconomic High-resolution Rural-Urban Geographic Platform for India (SHRUG). Elevation is defined as the average elevation in meters of each district while terrain ruggedness is the Terrain Ruggedness Index expressing elevation differences between adjacent pixels. The nightlights luminosity index aims to capture economic activity by detailed regions. Finally, court congestion is taken from the Development Data Lab and measures the average delay in days for the courts in each district.

C.2 Model probabilities -additional analysis

Figure A7: Model probabilities, Productivities and Distance

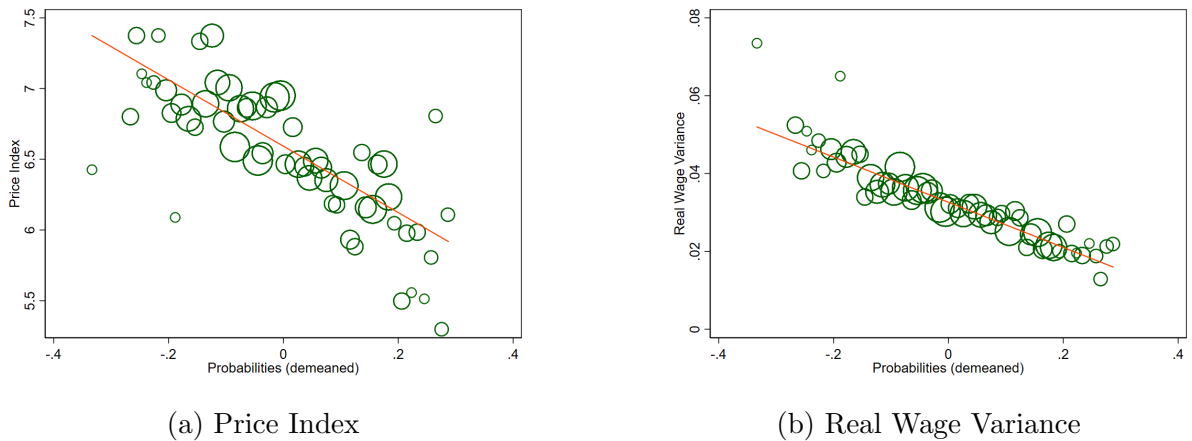

Note. In this figure, we plot the estimated probabilities against some observables. In the left panel, we correlate the probabilities with $\text{Log}(\text{Productivities})$. In the right panel, we correlate the probabilities with the average distance to the state of our study.

Table A2: Regression of model probabilities on observables

	Historical	Projected (2050)	Historical	Projected (2050)
Log Daily Rainfall	0.0350** (0.0143)	0.00388 (0.00884)	0.0498*** (0.0182)	0.00364 (0.00942)
Log Coastal Flooding	0.226 (0.164)	0.184 (0.120)	0.112 (0.183)	0.112 (0.137)
Log Riverine Flooding	0.0264 (0.0669)	0.149*** (0.0497)	-0.0167 (0.0696)	0.134** (0.0527)
Log Avg Temperature	-0.0175 (0.0432)	-0.0296 (0.0415)	-0.0321 (0.0524)	-0.0321 (0.0503)
Log Avg Nightlights Luminosity			0.00122 (0.0103)	-0.000116 (0.0102)
Log Avg Elevation			-0.00577 (0.00725)	-0.00727 (0.00702)
Log Avg Ruggedness			-0.0213 (0.0168)	0.00294 (0.0142)
Log Avg Court Congestion			-0.0124 (0.0626)	0.0115 (0.0634)
N	271	271	271	271
adj. R-sq	0.027	0.043	0.031	0.033

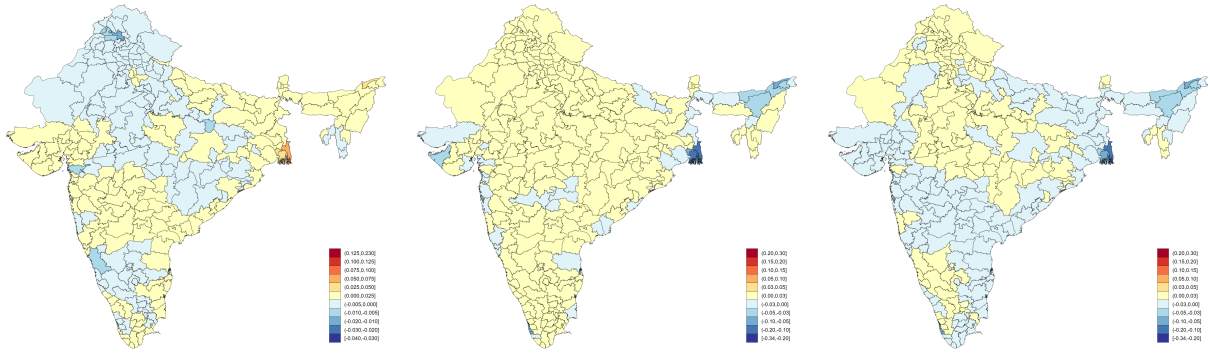

Note. *** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$. We run regressions of the log model probabilities on observables. In columns 1 and 3, climate variables used are measured with their historical values. In columns 2 and 4, climate variables used are measured with the projected values for 2050. Observables are also logged. A more detailed definition of each of the variables can be found in Appendix C.2.

Figure A8: Shock probabilities, Price Indices and Wages

Note. In this figure, we plot the model-derived price index (left panel) and real wage variance (right panel) against the estimated shock probabilities.

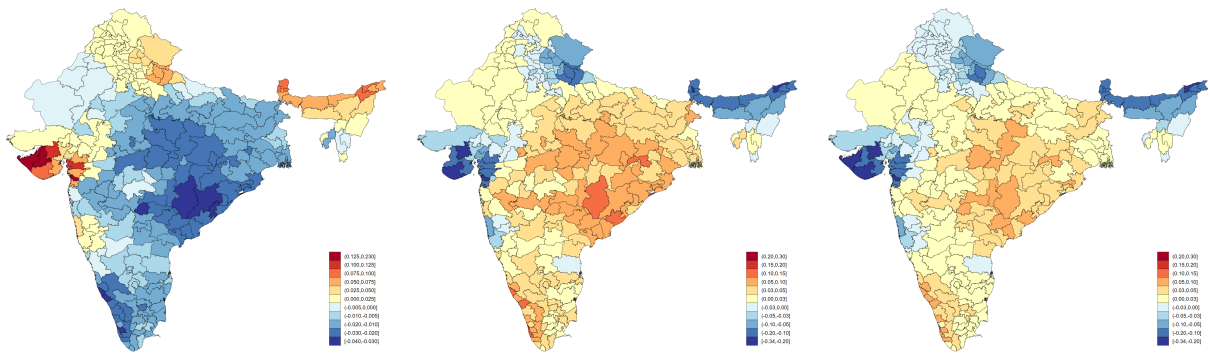

Figure A9: Counterfactuals: Flood Risk Increase

(a) Flood risk change (b) % Δ input prices (c) % Δ Expected Real Wages

Note. In this figure, we plot the change in probabilities of flood risk (left panel), the change in district input prices (middle panel) and the change in expected real wages (right panel) as flood risk increases as described in Section 4.4.

Figure A10: Counterfactuals: Precipitation Risk Increase

(a) Flood risk change (b) % Δ input prices (c) % Δ Expected Real Wages

Note. In this figure, we plot the change in probabilities of precipitation (left panel), the change in district input prices (middle panel) and the change in expected real wages (right panel) as flood risk increases as described in Section 4.4.
